BIOSILICIFICATION

The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges, molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants. See entries “*Silica Biomineralization, Sponges*”, “*Microbial Silicification – Bacteria (or Passive)*” and “*Microbial Biomineralization*” for further reading.

BLACK SHALES

Wolfgang Oschmann
 University of Frankfurt, Frankfurt, Germany

Definition

Most modern and ancient aquatic (marine, brackish, and lacustrine) environments were sufficiently oxygenated to permit colonization by numerous benthic, planktic, and nectic organisms. Due to excess oxygen the biologically produced organic matter is rapidly degraded. The sediments formed thereby exhibit only very low amounts of organic matter.

In contrast, very high rates of primary production and/or stagnant water bodies result in black shale sedimentation, which is associated with oxygen depletion or even lack of oxygen within the substrate and to some extent also within the water column. Degradation of organic matter is incomplete, partly by anaerobic bacteria, causing strong enrichment of organic matter in sediments. Black shales therefore commonly exhibit excellent preservation of organic molecules and mineralized soft tissues and hard parts of organisms.

The importance of black shales for scientists and the society are twofold. Black shales serve as source rocks for fossil fuels (oil and gas), which cover most of the energy needs of modern societies, and due to excellent preservation they provide particular sites for palaeontological studies.

Sedimentary characteristics of black shales

Black shales sediments in common are dark gray to black in color and are characterized by microlaminations, which may vary from distinct to blurred. The lamination is caused by quiet depositional conditions and the scarcity or lack of bioturbation. In many cases, the lamina were formed by alignments of fecal pellets ([Figure 1a](#)), which rained down in great numbers from surface waters. The

Black Shales, Figure 1 (a) Indistinct type of lamination formed by alignments of fecal pellets within bituminous mudstone facies (Kimmeridge Clay, Yorkshire, England, thin-section). (b) Most pellets are rich in carbonate and consist of coccoliths and coccospheres (Kimmeridge Clay, Yorkshire, England, SEM-view). (c) Organic rich filamentous mat-structures of bacterial origin (orange color) with dispersed silt-sized sedimentary particles (white) and pyritic aggregates (black) (thin-section, Kimmeridge Clay, Yorkshire). (d) SEM-view of a framboidal pyrite consisting of pyritohedral microcrystals precipitated during iron and sulfate reduction (Kimmeridge Clay, Yorkshire).

diameters of fecal pellets exceed the average annual sedimentation rate by far, and cause indistinct to blurred types of lamination. Commonly, it is assumed that seasonal variation in sedimentation (clastic input vs. primary production) may cause microlamination. However, the low sedimentation rates in general practically hamper a clear proof of varves.

Black shales typically consist of four main components (e.g., Röhl et al., 2001). *Siliciclasts*, mainly clay to silt sized particles form the major component of the rocks (50 to >90 wt.%). They derive from fluvial or aeolian input from hinterland areas. *Carbonates* originate either as skeletal remains of phytoplankton organisms (e.g., coccoliths, Figure 1b), or they are precipitated during early diagenesis at or close to the sediment surface (Frimmel et al., 2004). Their content varies remarkably. The proportion of *organic matter* may vary between 0.5 and 50 wt.% of the whole rock. It mainly derived from surface water primary production, but detritus from land plants and bacterial organic matter may also contribute. Black shales with a content of organic matter below 10% are termed as bituminous mudstones, and above 10% as oil shales. *Pyrite* (FeS_2) in black shales occurs as finely dispersed tiny framboids (Figure 1d), which were formed as syngenetic precipitates due to bacterially driven iron- and sulfate-reduction. In case of excess organic matter, larger pyrite aggregates may be formed during

diagenesis. The proportion of pyrite reaches 10–20 wt.% maximum.

History of organic matter preservation

During the early history of the Earth and life (Hadean and Archaean periods), virtually no free oxygen existed in the ocean and atmosphere. After oxygenic photosynthesis was established and the formerly reduced compounds had been oxidized, free oxygen started to accumulate in the ocean and the atmosphere ca. 2.2 billion years ago (e.g., Catling and Claire, 2005; Rouxel et al., 2005). The first eukaryotic organisms with highly resistant organic cell walls (acritarchs and/or primitive green algae) evolved during late early Proterozoic times (e.g., Samuelsson et al., 1999; Arouri et al., 2000). Their remains escaped rapid degradation and formed a major sink for organic carbon. Large quantities of organic matter had been embedded within marine sediments, leading to the first black shale formation (e.g., Banerjee et al., 2006). At least since Phanerozoic times, the atmosphere showed roughly the present-day oxygen levels (Catling and Claire, 2005; Berner, 2006) and aerated conditions persisted in the oceans. However, certain climatic and geographic factors promoted sluggish circulations with reduced turn over rates, thus preventing mixing of the water column. Related environments are commonly

controlled by a temporary or permanent density-stratification (thermo- and/or halocline) within the water column (e.g., Demaison and Moore, 1980; Oschmann, 1988; Wignall, 1994).

Oceanographic models for oxygen depletion and black shale formation

Certain combinations of physical and biotic factors cause oxygen depletion within marine areas, and have been described in various models from modern and ancient environments. In the following, a brief overview on the various models and fossil examples are given. Fossil examples in many cases however, were described in more than one of these models.

Silled basins

Land - locked silled basins with a positive water balance and a shallow and narrow connection to the open sea are characterized by a low salinity surface water outflow and a high salinity deeper water inflow (estuarine circulation). The difference in density between low and high salinity waters results in a permanent halocline and subsequently, thermocline. As convection and influx of oxygen to lower parts of the water column are prohibited, anoxic conditions develop below the halocline. The Baltic Sea and the Black Sea (e.g., Bahr et al., 2005, 2006) represent modern examples. Proposed fossil examples are e.g., the Permian Kupferschiefer (e.g., Bechtel and Püttmann, 1997) and Toarcian black shales in Central Europe (e.g., Röhl et al., 2001; van de Schootbrugge et al., 2005).

Upwelling systems

Today, upwelling is known from western continental margins in subtropical areas. Trade winds cause an offshore flow of surface waters and force oxygen-poor and nutrient-rich bottom waters to ascend. The mixing with oxygen-rich surface waters results in a very high plankton productivity and export production to the sea floor. Decomposition consumes all available oxygen, resulting in stagnant conditions and enrichment of organic matter in and on the sediment. Well-known modern to Pleistocene examples are the coastal areas off Peru and off Namibia (e.g., Wefer et al., 1996; Berger and Wefer, 2002; Hebbeln et al., 2002).

Oceanic anoxic events (OAEs)

Oceanic anoxic events (OAEs) were characterized by oxygen depletion in intermediate waters in major parts or even complete ocean basins. They were explained by a number of factors, namely (1) intensified deep water formation in high latitudes, (2) origin of warm and saline bottom waters at low latitudes, (3) enhanced fresh water runoff from continents associated with high rates of nutrient delivery, and (4) increased primary production associated with extreme greenhouse conditions. These factors all favor the development of low oxic to anoxic conditions with increased organic matter preservation. A modern to

Pleistocene example is the Arabian Sea in the low-latitude Indian Ocean (e.g., Schmiedl and Mackensen, 2006). Numerous OAEs occurred during the Earth's history, of which the Cretaceous OAEs are the most widely known. They are explained by high organic carbon burial related to global warming and greenhouse periods (e.g., Erbacher et al., 2001; Herrle et al., 2003). Many of these events were probably regional occurrences within restricted basins. However, there is increasing evidence for an open ocean and maybe global extension of the OAE 2 at the Cenomanian/Turonian boundary (e.g., Erbacher et al., 2005).

Eutrophic shelf

Many modern shelf environments (e.g., North Sea and Adriatic Sea) are characterized by man-made eutrophication that stimulates primary production with subsequent oxygen consumption and accumulation of organic matter (Dethlefsen and von Westernhagen, 1983; Kollmann and Stachowitsch, 2000). Fossil examples refer to a number of epicontinental seas particularly during the periods of greenhouse climate (e.g., Kimmeridge clay in western Europe (Oschmann, 1990; Miller, 1991), Toarcian black shales (van de Schootbrugge et al., 2005)).

Tidal mud flats and shallow lagunal environments

Most of the land-derived organic matter is deposited in near-shore environments, particularly in tidal mud flats. Additionally, land-derived nutrients stimulate primary production and subsequent oxygen depletion, thus promoting the enrichment of organic matter in the sediment (e.g., Wilms et al., 2006; Rink et al., 2007). Well-known fossil examples refer to the middle and late Triassic tidal and shallow subtidal mud flat areas from the northern Tethyan margin, e.g., at Mt. St. Giorgio, Switzerland (Röhl et al., 2002) and Seefeld, Austria (Hopf et al., 2001).

Black shales as ecosystems

Black shales and modern oxygen-depleted environments show various geochemical and ecological characteristics indicative of increasingly harsh life conditions (Table 1). Rhoads and Morse (1971) distinguished aerobic, dysaerobic, and anaerobic biofacies within marine environments. This classification has subsequently been used in many studies of modern and ancient oxygen-controlled environments (e.g., Tyson and Pearson, 1991; Wignall, 1994). Observations from modern environments show a remarkable seasonal oxygen fluctuation (Oschmann, 1994, 2000). Therefore, a modified scheme of classification was introduced, where the term dysaerobic was replaced by poikiloaerobic to address seasonal variation in oxygen supply.

The proportions of organic matter, pyrite, and biomarkers increase from the aerobic toward the anaerobic biofacies. In the same direction, the diversity of eukaryotes diminishes. Particularly, deep burrowing organisms

Black Shales, Table 1 A synoptic sketch of the geochemical and ecological characteristics of modern and fossil aerobic, dysaerobic/poikiloaerobic, and anaerobic biofacies

Biofacies			Aerobic	Dysaerobic/poikiloaerobic			Anaerobic

Position of redox boundary:		Deep in substrate	Close to sediment surface			Within the water column	

are affected by the rise of the redox boundary and try to settle close to the sediment surface (Oschmann, 1994; Schmiedl and Mackensen, 2006). Additionally, the proportion of organisms with benthic (lecithotrophic) larval development decreases with increasing oxygen depletion. If the redox boundary finally migrates out of the substrate, eukaryotic life is excluded. Dwarfs with body size remarkably smaller than normal and juveniles occur within the dysaerobic/poikiloaerobic facies, whereas microbial mats and partly also larval shells can be found within the anaerobic facies. The sporadic occurrence of the latter indicates failed larval spatfalls during unfavorable conditions.

Conclusions

1. Black shale sediments mainly form in marine to brackish waters under low oxic to anoxic conditions.
2. They are characterized by remarkably enriched proportions of organic matter and pyrite. The organic matter derives from marine primary production, terrestrial input, and bacterial derived compounds.
3. Black shales date back to late Proterozoic times and are widespread during Phanerozoic age.
4. Origination of black shales is explained by a number of models. A common aspect of most of these models is the formation of a density stratified water column, which prevents oxygenation of deeper waters.

5. The degree of oxygen depletion in benthic ecosystems during black shale deposition can be reconstructed by a number of geochemical and ecological features.

Break-up of the supercontinent Rodinia

Definition

Supercontinent Rodinia. The earth's geodynamic system periodically pushes almost all continents together to form a single landmass – a supercontinent. The best known supercontinent is Pangaea (or Pangea) that existed between 320 and 170 Ma. A less known supercontinent Rodinia is believed to have existed between 900 Ma (some believe 1,000 Ma) and 750 Ma. The name “Rodinia” was coined by McMenamin and McMenamin (1990) from the Russian word “rodit” meaning “to beget” or “to give birth.” McMenamin and McMenamin (1990, p. 95) considered Rodinia to have been the supercontinent that spawned all subsequent continents, while “the edges (continental shelves) of Rodinia were the cradle of the earliest animals.” Three landmark paper in 1991 (Moores, 1991; Dalziel, 1991; Hoffman, 1991) triggered a global debate on this supercontinent hypothesis. The configuration of Rodinia is still controversial today, with some alternative reconstructions given in Hoffman (1991), Pisarevsky et al. (2003), and Li et al. (2008) (Figure 1).

The breakup of Rodinia: introduction

Although it is widely accepted that Rodinia broke apart during the latter half of the Neoproterozoic era (1,000–542 Ma) and that some fragments reassembled by the early Cambrian (*ca.* 530 Ma) to form Gondwanaland (Hoffman, 1991), our knowledge of the timing of the breakup events and the processes involved is still sketchy.

Record of Rodinia breakup

The breakup of Rodinia was recorded both geologically and geophysically. The most important geological records of the breakup process are globally widespread continental rift deposits and related magmatism, and records of the geological transition from continental rifting to passive margin deposits where rifting succeeded to form new oceans. One of the best matches of rifting records between continents is that between southeast Australia and South China, where episodes of rift-related magmatism at *ca.* 825 Ma, 800 Ma, 780 Ma, and 750 Ma have been well documented (Preiss, 2000; Li et al., 2003) (Figure 2). Similar records are emerging from other continents.

Radiating dyke swarms and remnants of large igneous provinces (LIPs) have also been regarded as important geological records of the breakup of Rodinia (Figure 2c and d; see discussion below under *Mechanism for the breakup*).

The most important geophysical constraint on the breakup of Rodinia is provided by paleomagnetism. Whereas, an individual pole of a given age for a continent constrains its paleolatitude at that time but not its paleolongitude, comparable apparent polar wander paths (APWPs) for different continents can indicate a unique paleogeographic fit between them. In the latter case, when two matched APWPs start to diverge, it implies that the two continents started to move independently (*i.e.*, a breakup between them occurred). Unfortunately, such an ideal situation has rarely been identified for the Rodinia time because of the limited data currently available.

Timing of events

The ages of continental rifting events can be easily dated because of the availability of datable minerals such as zircon in the rift-related magmatic rocks, and it is now widely accepted that continental rifting in the lead-up to Rodinia breakup started at *ca.* 825 Ma or earlier (see summary in Li et al., 2008; Figure 2). However, the timing of the breakup events is still controversial, and different parts of the supercontinent seem to have broken apart at different times.

The stratigraphic record in southeast Australia indicates a rift-drift transition between the Sturtian glacial deposits (with a poor age constraint of *ca.* 750–690 Ma) and the overlying sag-phase deposits (Powell et al., 1994) that were recently dated at between 657 ± 5 and 643 ± 2 Ma (Re-Os ages, see Kendall et al., 2006). These age

The breakup of Rodinia was recorded both geologically and geophysically. The most important geological records of the breakup process are globally widespread continental rift deposits and related magmatism, and records of the geological transition from continental rifting to passive margin deposits where rifting succeeded to form new oceans. One of the best matches of rifting records between continents is that between southeast Australia and South China, where episodes of rift-related magmatism at *ca.* 825 Ma, 800 Ma, 780 Ma, and 750 Ma have been well documented (Preiss, 2000; Li et al., 2003) (Figure 2). Similar records are emerging from other continents.

Radiating dyke swarms and remnants of large igneous provinces (LIPs) have also been regarded as important geological records of the breakup of Rodinia (Figure 2c and d; see discussion below under *Mechanism for the breakup*).

The most important geophysical constraint on the breakup of Rodinia is provided by paleomagnetism. Whereas, an individual pole of a given age for a continent constrains its paleolatitude at that time but not its paleolongitude, comparable apparent polar wander paths (APWPs) for different continents can indicate a unique paleogeographic fit between them. In the latter case, when two matched APWPs start to diverge, it implies that the two continents started to move independently (*i.e.*, a breakup between them occurred). Unfortunately, such an ideal situation has rarely been identified for the Rodinia time because of the limited data currently available.

Timing of events

The ages of continental rifting events can be easily dated because of the availability of datable minerals such as zircon in the rift-related magmatic rocks, and it is now widely accepted that continental rifting in the lead-up to Rodinia breakup started at *ca.* 825 Ma or earlier (see summary in Li et al., 2008; Figure 2). However, the timing of the breakup events is still controversial, and different parts of the supercontinent seem to have broken apart at different times.

The stratigraphic record in southeast Australia indicates a rift-drift transition between the Sturtian glacial deposits (with a poor age constraint of *ca.* 750–690 Ma) and the overlying sag-phase deposits (Powell et al., 1994) that were recently dated at between 657 ± 5 and 643 ± 2 Ma (Re-Os ages, see Kendall et al., 2006). These age

Breakup of Rodinia, Figure 1 Three of the alternative Rodinia reconstructions: (a) Hoffman (1991), (b) Pisarevsky et al. (2003), and (c) model adapted by IGCP440 for the Geodynamic Map of Rodinia. (Li et al., 2008.)

constraints seem to agree with those for south China and western Laurentia. Although rifting occurred at *ca.* 750 Ma along the eastern margins of Laurentia, the breakup there appears to have occurred during *ca.* 615–570 Ma (Cawood and Pisarevsky, 2006). These younger events are possibly recognizable in global tectonic subsidence curves (Bond et al., 1984).

Such geological evidence for the breakup of Rodinia is sometimes at variance with paleomagnetic constraints. Paleomagnetic data suggests that India was either adjacent to western Australia (Torsvik et al., 2001) or had already broken away from Rodinia at 750 Ma (Figure 3b). South

China must also have broken away from Australia and Laurentia by 750 Ma if it occupied a central position in Rodinia as shown in Figures 1c and 3a (Wingate and Giddings, 2000; Li et al., 2008). Alternatively, Rodinia may have remained intact at *ca.* 750 Ma if a different configuration occurred (see Fig. 5 of Li et al., 2004).

Mechanism for the breakup

The most commonly invoked mechanism for the breakup of Rodinia is the activity of mantle plumes or of a mantle superplume (superswell) beneath the supercontinent,

Breakup of Rodinia, Figure 3 Cartoons illustrating the breakup process of Rodinia. (After Li et al., 2008.)

which thinned and thermally weakened the lithosphere resulting in widespread continental rifting and eventually breakup (Figure 3a and b).

Evidence for plume/superplume activity during the time of Rodinia include remnants of LIP and radiating dyke swarms (Figure 2c), syn-magmatic, continental-scale doming indicating the arrival of a plume-head (Li et al., 1999), large-scale anorogenic but often dominantly felsic melting that requires a pan-Rodinia introcontinental heat source (Li et al., 2003), and abnormally high-temperature ($>1,500^{\circ}\text{C}$) mantle melting (Wang et al., 2007). Mechanisms proposed for the formation of such a superplume (or superswell) include thermal shielding by the supercontinent (e.g., Anderson, 1994), gravitational push-up effects on the hotter lower mantle by circum-Rodinia avalanching slabs (Li et al., 2004, 2008), return flow of whole-mantle convection (Zhong et al., 2007), and partial melt of recycled mid-ocean ridge basalts near the core-mantle boundary under Rodinia (Maruyama et al., 2007).

Summary

The breakup of Rodinia was a diachronous and protracted process. Widespread continental rifting started at *ca.* 825 Ma when Rodinia spanned from the equator to high latitudes (Figure 3a), but the breakup, initially between Australia/East Antarctica, Laurentia, and possibly South China did not occur until *ca.* 750 Ma (Figure 3b) or later when the supercontinent was centered on the equator. Gondwanaland was already assembling before some of the West Gondwanan continents broke away from Laurentia at *ca.* 600 Ma (Figure 3c), and by the early Cambrian (530 Ma) the assembly was complete (Figure 3d). The breakup of Rodinia is believed by some to have been related to the formation of a mantle superplume beneath the supercontinent.

CALCAREOUS ALGAE

The term “calcareous algae” refers to various kinds of benthic and planktonic algae whose thalli contain biochemically precipitated calcium carbonate (CaCO_3) as skeletal material (Wray, 1977; Braga and Riding, 2005). Precipitation of CaCO_3 (as calcite and/or aragonite) may occur within or on the algal bodies. The term may also include mechanically accreted deposits of calcium carbonate caused by algae, usually as an interaction of biological and physical processes. Calcareous algae are a highly artificial group that constitutes calcifying members of the Chlorophyta (green algae), Rhodophyta (red algae), and Phaeophyta (brown algae) and is sometimes also used for Cyanobacteria. At present, calcareous algae are one of the most important reef builders (see “[Carbonate Environments](#)”). For a detailed reading, please refer to “[Algae \(Eukaryotic\)](#).”

CALCIFIED CYANOBACTERIA

Robert Riding
University of Tennessee, Knoxville, TN, USA

Definition

Cyanobacteria are alga-like bacteria that can perform oxygenic photosynthesis and nitrogen fixation (Whitton and Potts, 2000; Herrero and Flores, 2008). They have a long history and are diverse and widespread in marine, freshwater, and terrestrial environments at the present-day, where they are key primary producers in both microbial mat and planktic ecosystems. As the initiators of plastids, they have played a fundamental role in algal and plant evolution (Raven, 2002). Cyanobacteria occupy benthic substrates and can also drift in the water column. Their photosynthetic uptake of inorganic carbon can stimulate CaCO_3 precipitation. This calcification can produce filamentous microfossils in benthic mats that are preserved as stromatolites and thrombolites, and can also cause water column precipitation of carbonate mud that settles to lake and sea floors.

Introduction

However, cyanobacterial calcification is not obligatory and is directly dependent on environmental conditions. This accounts for apparent discrepancies between the geological ranges of organic-walled and calcified cyanobacterial fossils. Calcified cyanobacteria have not been recognized in marine sediments older than ~1200 Ma ago (Kah and Riding, 2007), whereas there is evidence that cyanobacteria appeared in the late Archaean or Palaeoproterozoic, in the range ~2900–2150 Ma ago (Cavalier-Smith et al., 2006; Hofmann, 1976). This mid-Proterozoic appearance of sheath-calcified cyanobacteria is thought to reflect the development of CO_2 -concentrating

CALCIUM BIOGEOCHEMISTRY

Anton Eisenhauer
 IFM-GEOMAR, Christian Albrechts Universität zu Kiel,
 Kiel, Germany

Definition

Calcium (Ca) has the atomic number 20 and is an alkaline earth metal with an atomic mass of 40.978 amu. The

important role of Ca in biogeochemical processes is based on its chemical versatility, which is related to its highly adaptable coordination geometry, its divalent charge, modest binding energies, fast reaction kinetics, and its inertness in redox reactions (Williams, 1974). Calcium is a soft grey alkaline earth metal, and is the fifth most abundant element in the Earth's crust and the seventh most abundant element in the ocean. It is essential for living organisms, particularly in cell physiology, shell formation, and calcification and hence, is usually the most common metal in many animals.

Calcium isotopes and their application in Biogeochemistry

There are seven Ca isotopes present in nature of which three isotopes (^{42}Ca (0.646%), ^{43}Ca (0.135%) through ^{44}Ca (2.086%)) are stable, one isotope (^{40}Ca (69.941%)) is radiogenic, one isotope (^{41}Ca) is cosmogenic, and two more isotopes (^{46}Ca (0.004%) and ^{48}Ca (0.187%)) are radioactive having extremely long half-lives (^{46}Ca : $2.8 \cdot 10^{15}$ years; ^{48}Ca : $> 4 \cdot 10^{19}$ years). The cosmogenic isotope ^{41}Ca is radioactive (half live of 103,000 years) and is produced by neutron activation of ^{40}Ca in the upper soil column. ^{41}Ca has received much attention in stellar studies because it decays to ^{41}K , a critical indicator of solar system anomalies. ^{40}Ca is the radiogenic daughter product of ^{40}K decay, along with ^{40}Ar . While K–Ar dating has been used extensively in the geological sciences, the prevalence of ^{40}Ca in nature has impeded its use in dating. Techniques using mass spectrometry and a double spike isotope dilution have been used for K–Ca age dating (Nägler and Villa, 2000).

Natural Ca isotope fractionation has, among other isotope systems such as oxygen (d^{18}O) and carbon (d^{13}C) fractionation, been applied for the study of calcification processes and the so-called vital effect (c.f. Gussone et al., 2003; Lemarchand et al., 2005). Latter effect describes the deviation of the expected inorganic isotope fractionation value or element partitioning coefficient (e.g., Sr/Ca, Mg/Ca, etc.) from the measured one in calcifying organisms such as coccolithophores, foraminifer, corals, and other calcifying organisms.

The more or less species-dependent Ca isotope fractionation of marine calcifying organisms as a function of the adjacent seawater temperature can be applied for the reconstruction of the dynamic of Ca concentrations throughout the Earth's history (c.f. Griffith et al., 2008; Farkas et al., 2007; Heuser et al., 2005; Fantle and DePaolo, 2005; De LaRocha and DePaolo, 2000) and for the reconstruction of past sea surface temperatures (c.f. Nägler et al., 2000; Hippler et al., 2006).

The dynamic of calcium in the ocean

Calcium is the second most abundant divalent cation (~ 10 mmol/l), besides magnesium (Mg, ~ 52 mmol/l). Calcium is considered to be a conservative element in the ocean water column, with a residence time of about

one million year. A number of scientific studies show that continental and oceanic weathering, mid-ocean ridge hydrothermal activity, and carbonate sedimentation are the major factors controlling the marine Ca cycle (Hart, 1973; Thompson, 1983; Zhu & Macdougall, 1998; Berner, 2004). Besides continental weathering and riverine influx, comprising about 70% of the Ca flux to the ocean, submarine magmatism and associated hydrothermal activity at the mid-ocean ridges as well as seafloor weathering are also recognized to be major sources for the marine Ca budget (Berner & Berner, 1996). A number of studies indicated that Ca is released from the oceanic crust during water–rock reactions ranging from high-temperature hydrothermal interactions to seafloor weathering at low temperatures below about 150°C (Berner, 2004; Amini et al., 2008). Ca-bearing mineral phases such as aragonite, calcite, anhydrite, and subordinately hydrous Ca-silicates (e.g., prehnite, zeolites) are formed during different stages of ocean crust alteration.

Marine calcification

The dynamic of Ca in the ocean is of particular interest because of the formation of biogenic and nonbiogenic calcium carbonate (CaCO_3), known as the process of calcification, and its interference and close linkage with the global carbon cycle (c.f. De LaRocha & DePaolo, 2000; Heuser et al., 2005). In particular, the formation of calcareous skeletons by marine planktonic organisms and their subsequent sinking to depth generate a continuous rain of CaCO_3 to the deep ocean and the underlying sediments. This is important in regulating marine carbon cycling and ocean–atmosphere CO_2 exchange. The present rise in atmospheric CO_2 levels causes a significant decrease (acidification) in surface ocean pH and a major change of carbonate chemistry. Laboratory experiments have shown that such changes slow down calcification in corals and coralline macroalgae. Over geological time scales, the Ca balance in the ocean is believed to be directly related to pCO_2 variations in the atmosphere, and it thus may interfere with climate changes on geological time scales (e.g., Demicco et al., 2003; Fantle and DePaolo, 2005).

Summary

Future progress in instrumental analytic will allow high-resolution measurement of Ca elemental and isotope partitioning in inorganic and biological systems, allowing to trace elemental pathways from a bulk solution to the site of calcification.

CALCITE PRECIPITATION, MICROBIALY INDUCED

Tanja Bosak

Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Microbially induced calcite precipitation describes the formation of calcium carbonate minerals from a solution due to the presence of microbial cells, biosynthetic products, or metabolic activity.

Calcium carbonate precipitation

The most basic requirement for the precipitation of calcium carbonate (CaCO_3) minerals, calcite, and aragonite is that the product of the concentrations of calcium $[\text{Ca}^{2+}]$ and carbonate ions $[\text{CO}_3^{2-}]$ exceeds the solubility product of calcite (Equation 1) and aragonite, respectively.

$$[\text{Ca}^{2+}][\text{CO}_3^{2-}] > 10^{-8.35} \quad (1)$$

The solubility of carbonate minerals depends on the temperature and pressure, decreasing with increasing temperatures and increasing with the increasing pressure. When a solution is in equilibrium with carbon dioxide, $[\text{CO}_3^{2-}]$ is determined by pH. In solutions that are undersaturated or not highly saturated, such as modern seawater, the biological activity can strongly control the precipitation of CaCO_3 . Biological processes exert considerably less control on the precipitation of CaCO_3 in environments characterized by high temperature, high pH, and high evaporation and degassing rates such as soda lakes, hot springs, caves, and freshwater tufas.

Microbial processes that promote the precipitation of CaCO_3

Culture-dependent and culture-independent studies have shown that microbes (Bacteria and Archaea) can induce extracellular precipitation of calcium carbonate minerals by:

- Increasing the local pH and the concentration of carbonate ion
- Promoting the nucleation of calcium carbonate minerals and removing the kinetic inhibitors of CaCO_3 precipitation.

Increase in local pH and the concentration of carbonate ion

Because the concentration of carbonate ion increases with the increasing pH, the precipitation of calcium carbonate minerals will also increase with the increasing pH. Many microbial metabolic processes can increase the pH and/or the concentration of carbonate ions: sulfate reduction in marine sediments (Dupraz and Visscher, 2005; Van Lith et al., 2003; Visscher et al., 2000), oxygenic

photosynthesis in freshwater streams and lakes (Merz-Preiß and Riding, 1999; Thompson et al., 1997), anaerobic methane oxidation coupled with sulfate reduction in marine sediments (Reitner et al., 2005), denitrification, degradation of amino-acids and small organic acids (Chekroun et al., 2004), and degradation of calcium oxalate in soils (Braissant et al., 2002). Whether microbes are able to significantly increase local pH and $[\text{CO}_3^{2-}]$ will largely depend on the buffering of the medium by dissolved inorganic carbon. Microbial activity in poorly buffered solutions such as lakes and streams is more likely to influence the saturation state of CaCO_3 (Merz-Preiß and Riding, 1999) than in well-buffered solutions such as soda lakes, hot springs, and solutions analogous to the early soda oceans (Arp et al., 1999a, b; Bosak and Newman, 2005).

Precipitation of calcium carbonate minerals also can be inhibited by the adsorption of various metabolites such as phosphate, sulfate, and organic moieties onto the faces of the growing crystals (Bosak and Newman, 2005; Liu and DeYoreo, 2004; Plant and House, 2002; Teng et al., 1998). Microbial growth and metabolic processes that lower the concentration of these ions in the solution can promote the precipitation of minerals even when they do not significantly influence pH and $[\text{CO}_3^{2-}]$ (Bosak and Newman, 2005; Kawaguchi and Decho, 2002).

Nucleation of calcium carbonate minerals on organic surfaces

Minerals can nucleate either homogeneously on the surface of preexisting carbonate grains, or heterogeneously on organic or other surfaces. When the external calcium carbonate sediment is sparse or absent, nucleation is the most energetically expensive step in the precipitation of calcium carbonate minerals. Organic matter can lower the free energy barrier required to form the initial nuclei, thus promoting mineral formation. Nucleation of CaCO_3 on organic surfaces (i.e., heterogeneous nucleation) occurs when negatively charged surface groups such as carboxylate, phosphate, and sulfate complex bind calcium. Although this process can initially inhibit the precipitation of minerals, once the local concentrations of calcium and carbonate has exceeded the binding capacity of the organic matrix, or when the matrix is partially degraded, mineral nucleation occurs preferentially on the organic template (Arp et al., 2003; Braissant et al., 2003; Decho et al., 2005). Heterogeneous nucleation can increase the number of crystal nuclei even when the bulk medium is supersaturated with calcium carbonate by more than an order of magnitude (Arp et al., 1999b; Bosak and Newman, 2003).

Heterogeneous nucleation of CaCO_3 can take place on the cell surfaces and envelopes, or within the exopolymeric matrix surrounding microbial cells. Examples of the former are the calcification of the sheaths surrounding cyanobacterial cells (Merz-Preiß and Zankl, 1993) and the whitening events caused by the precipitation of calcite on the outer S-layer of some planktonic

cyanobacteria (Thompson et al., 1997). These processes are most commonly observed in freshwater environments and require actively photosynthesizing cyanobacteria (Thompson et al., 1997). Cyanobacteria encrusted by CaCO_3 are considerably less abundant in modern marine calcium carbonates (Arp et al., 2001). Similarly, the relationship between marine whittings and cyanobacterial presence and activity has not been demonstrated conclusively (Thompson, 2000). Instead, in marine photic zones, carbonate minerals precipitate mainly within the extracellular exopolymeric matrix in areas of heterotrophic degradation (Chafetz and Buczynski, 1992; Dupraz and Visscher, 2005; Gautret et al., 2006; Van Lith et al., 2003; Visscher et al., 2000). In addition to the nucleation on exopolymeric substances or cell surfaces, CaCO_3 also preferentially nucleates around submicron vesicles that are secreted by sulfate-reducing bacteria (Aloisi et al., 2006). The nucleation of CaCO_3 on these vesicles may be a common mechanism in the environment, because outer-membrane vesicles are secreted by many Gram-negative bacteria (Beveridge, 1999; Kuehn and Kesty, 2005).

Recognition of microbially induced CaCO_3 precipitates in the rock record

Even when microbes do not induce measurable changes in the chemical composition of the bulk solution, they can alter the pH and carbonate chemistry, remove kinetic inhibitors, and promote mineral nucleation and precipitation at a microscale (Figure 1). When minerals precipitate, surrounded by microbial cells and microbial aggregates (biofilms) (Figure 1), they can preserve remnants of organic matter, such as acidic amino acids and microbial casts, long after the original cells have been degraded (Bosak et al., 2004a; Sprachta et al., 2001). Furthermore, CaCO_3 precipitated in the presence of organic compounds often has distinct shapes (Bosak and Newman, 2005; Braissant et al., 2003; Chafetz and Buczynski, 1992; Teng et al., 1998), although similar shapes can also be produced abiotically.

Biological influence on the morphology of carbonate crystals and structures is most prominent in skeleton-building organisms. Macroscopic and microscopic eukaryotic organisms such as calcareous algae, protists, corals, and mollusks precipitate hard body parts. Many of these organisms precipitate CaCO_3 by genetically encoded mechanisms that result in shells, skeletons, and carbonate grains with species-specific shapes. In contrast to these products of biologically controlled calcification, the shapes of microbially induced carbonate minerals can be distinguished from abiotically precipitated grains rarely (Golubic et al., 2000). Consequently, the potential identification of biosignatures of microbially induced carbonates in modern and past sedimentary carbonates can be controversial (Grotzinger and Knoll, 1999).

Recognition of microbially induced carbonates is also impeded by the difficulty in distinguishing between CaCO_3 structures that grew *in the presence* of microbes

Calcite Precipitation, Microbially Induced, Figure 1 Aragonite precipitated on cyanobacterial biofilms (BF) floating in solution. (a) Photograph of a thin cyanobacterial biofilm with visible aragonite precipitates that preserve the biofilm. White arrows mark the densest mineral aggregates. (b) Transmitted-light micrograph of cyanobacterial filaments trapping small mineral grains (white arrows) in lightly mineralized areas. (c) Epifluorescence micrograph (deconvolved) of the same field of view as in (b). Cyanobacterial filaments fluoresce red and the nuclei of other microbes are stained green. Note that the mineral grains are surrounded by microbial aggregates that are not cyanobacteria (and are, presumably, heterotrophic). Scale bar: 5 mm in a, 5 μ m in b and c.

or organic matter from structures that grew *because* of microbial activity. Some examples of carbonate grains and structures with often ambiguous origin include peloids, ooids (Figure 2), whittings, fossil stromatolites, and nanobacteria. Recent developments in analytical techniques such as X-ray microscopy have enabled the detection of small quantities of fossil organic matrices in fossil carbonates at the microscale, thereby establishing that some fossil carbonates grew in the presence of microbes (Benzerara et al., 2006; Lepot et al., 2008). Despite the inclusion of organic matter, the role of biology in forming these structures remains unknown. As an alternative approach, experimental and quantitative models of the morphogenesis of sedimentary structures at the macroscale and microscale have been developed in an attempt to understand which fossil structures and shapes require biological processes (Batchelor et al., 2004; Bosak et al., 2004b; Dupraz et al., 2006; Grotzinger and Rothman, 1996; Reid et al., 2000; Suess and Futterer, 1972).

Summary

The potential of microbes to induce precipitation of calcium carbonate has sparked scientific interest for almost a century. The calcium carbonate (CaCO_3) minerals, calcite and aragonite, often precipitate in association with microbial cells and biofilms in marine and terrestrial sedimentary environments such as reefs, lakes, streams, beaches, soils, hot springs, and caves. Being ubiquitous and relatively insoluble, these minerals have helped preserve bacterial and archaeal cells and biofilms throughout geologic time (Figure 1). Microbes promote the precipitation of calcium carbonate metabolically, by increasing the pH and the alkalinity of their surroundings, or by the secretion of substances that facilitate the mineral nucleation. The recognition of microbially influenced calcium carbonate precipitates in the rock record is often challenging because abiotic carbonate precipitation can produce

Calcite Precipitation, Microbially Induced, Figure 2 An example of carbonate grains of controversial origin. Scanning electron micrograph of a thick polished section of late Jurassic ooids (rounded grains with layered interior structure) precipitated on the Adriatic Platform, Croatia, in low-energy, shallow water settings (Husinec and Reid, 2006). Ooids from low-energy environments were commonly interpreted as largely inorganic precipitates that adsorb organic molecules (Davies et al., 1978). More recently, cyanobacteria and other microbes have been shown to contribute to the formation of low-energy ooids and meniscus cements (M) (Brehm et al., 2006; Hillgartner et al., 2001; Plee et al., 2008). Although microbes may have contributed to the formation of ooids shown here, these grains do not preserve any textural evidence of the former presence of microorganisms. Scale bar: 100 μ m.

crystals with similar shapes and chemical signatures. Current research in the field of microbial carbonates tackles this challenge by conducting culture-dependent and culture-independent studies of microbial mineral precipitation, employing analytical techniques that can detect

small quantities of organic matter in fossil carbonates, and by developing theoretical models that explain the shape of macroscopic carbonate sedimentary structures. Microbially induced precipitation of carbonate minerals is likely to garner even more interest in the future with a primary focus on carbon sequestration, the production of biomimetic materials, and the conservation of ornamental stone.

CALCIUM BIOGEOCHEMISTRY

Anton Eisenhauer
 IFM-GEOMAR, Christian Albrechts Universität zu Kiel,
 Kiel, Germany

Definition

Calcium (Ca) has the atomic number 20 and is an alkaline earth metal with an atomic mass of 40.978 amu. The

important role of Ca in biogeochemical processes is based on its chemical versatility, which is related to its highly adaptable coordination geometry, its divalent charge, modest binding energies, fast reaction kinetics, and its inertness in redox reactions (Williams, 1974). Calcium is a soft grey alkaline earth metal, and is the fifth most abundant element in the Earth's crust and the seventh most abundant element in the ocean. It is essential for living organisms, particularly in cell physiology, shell formation, and calcification and hence, is usually the most common metal in many animals.

Calcium isotopes and their application in Biogeochemistry

There are seven Ca isotopes present in nature of which three isotopes (^{42}Ca (0.646%), ^{43}Ca (0.135%) through ^{44}Ca (2.086%)) are stable, one isotope (^{40}Ca (69.941%)) is radiogenic, one isotope (^{41}Ca) is cosmogenic, and two more isotopes (^{46}Ca (0.004%) and ^{48}Ca (0.187%)) are radioactive having extremely long half-lives (^{46}Ca : $2.8 \cdot 10^{15}$ years; ^{48}Ca : $> 4 \cdot 10^{19}$ years). The cosmogenic isotope ^{41}Ca is radioactive (half live of 103,000 years) and is produced by neutron activation of ^{40}Ca in the upper soil column. ^{41}Ca has received much attention in stellar studies because it decays to ^{41}K , a critical indicator of solar system anomalies. ^{40}Ca is the radiogenic daughter product of ^{40}K decay, along with ^{40}Ar . While K–Ar dating has been used extensively in the geological sciences, the prevalence of ^{40}Ca in nature has impeded its use in dating. Techniques using mass spectrometry and a double spike isotope dilution have been used for K–Ca age dating (Nägler and Villa, 2000).

Natural Ca isotope fractionation has, among other isotope systems such as oxygen (d^{18}O) and carbon (d^{13}C) fractionation, been applied for the study of calcification processes and the so-called vital effect (c.f. Gussone et al., 2003; Lemarchand et al., 2005). Latter effect describes the deviation of the expected inorganic isotope fractionation value or element partitioning coefficient (e.g., Sr/Ca, Mg/Ca, etc.) from the measured one in calcifying organisms such as coccolithophores, foraminifer, corals, and other calcifying organisms.

The more or less species-dependent Ca isotope fractionation of marine calcifying organisms as a function of the adjacent seawater temperature can be applied for the reconstruction of the dynamic of Ca concentrations throughout the Earth's history (c.f. Griffith et al., 2008; Farkas et al., 2007; Heuser et al., 2005; Fantle and DePaolo, 2005; De LaRocha and DePaolo, 2000) and for the reconstruction of past sea surface temperatures (c.f. Nägler et al., 2000; Hippler et al., 2006).

The dynamic of calcium in the ocean

Calcium is the second most abundant divalent cation (~ 10 mmol/l), besides magnesium (Mg, ~ 52 mmol/l). Calcium is considered to be a conservative element in the ocean water column, with a residence time of about

CAP CARBONATES

Joachim Reitner
University of Göttingen, Göttingen, Germany

Definition

Cap carbonates are unusual deposits of dolostones and limestones, often enriched in barite, that sharply overlie Neoproterozoic glacial deposits. They are from 2 to 50 m thick and occur on shallow platforms, shelves, and

Cap Carbonates, Figure 1 Marinoan ca. 635 My cap carbonate from Namibia (Fransfontein, Otavi Mountains). Characteristic features of this cap carbonate (mainly dolomite) are syndimentarily formed Zebra Limestone-type fabrics. The horizontal fractures were originally cemented with large aragonitic crystals. The remaining pore spaces are filled up with cherts.

Cap Carbonates, Figure 2 Sturtian ca. 750 My old cap carbonate from Namibia (Rasthof cap carbonate, Baesvalkte). These black laminated carbonates are lithified microbial mats. Very common are “roll up structures” which are known from many microbial mat systems, even from modern ones.

slopes worldwide, even in regions otherwise lacking in carbonate strata.

Glaciation events during the late Neoproterozoic (Cryogenian–Ediacaran) are widespread on Earth, reflecting up to four global ice ages (“Snowball Earth Hypothesis”) between 730 and 580 Ma. Numerous publications dealing with these events exist (for example, see Chapter by Hoffman P.F., Snowball Earth, this volume; Shields, 2005; Jiang et al., 2003). Some of them exhibit characteristic, microcrystalline cap dolostones, and also limestones, which is unique and reflects a climate paradox. Particularly the Marinoan glaciation ca. 635 Ma ago is peculiar, because it provides evidence for low altitude glaciation at equatorial latitudes. Three models have been proposed to explain an increase in alkalinity inducing these global carbonate formation events:

(1) Overturn of an anoxic deep ocean; (2) enormous rates of chemical weathering in the hinterland after glaciation (Snowball Earth Hypothesis); (3) destabilization of methane clathrates and increase of alkalinity caused by anaerobic oxidation of methane (AOM). However, none of the hypotheses sufficiently explains the consistent sequence of precipitation events observed within cap carbonate successions. The formation of massive dolostones is very problematic and hardly understood. Massive microbial sulfate reduction may explain this event. Barite precipitation is also very common. The source of sulfate is most probably the weathered hinterland. Caused by seawater oversaturated with aragonite, diagenetically very early large aragonite crystals were formed. It is suggested that cap carbonates are primarily formed by a microbially mediated precipitation. Possibly, the highly oxygenated shallow marine environments of the postglacial Neoproterozoic oceans provided excellent conditions for the evolutionary development of new microbial communities, phototrophic organisms, and of course, the rapid development of Metazoa (Figures 1 and 2).

CARBON (ORGANIC, CYCLING)

Amber K. Hardison, Elizabeth A. Canuel
Virginia Institute of Marine Science, Gloucester Point,
VA, USA

Definition

Organic carbon (OC) refers to any carbon that occurs in compounds of ultimately biological origin that can be oxidized.

Introduction

Carbon is made up of organic and inorganic fractions, and the biochemical and geochemical cycling of these forms through the Earth processes is referred to as the global carbon cycle. The global carbon cycle is closely linked to other global cycles such as oxygen, nitrogen, and sulfur because of the important role these elements play in biological processes. Organic carbon (OC) is present in both living and nonliving systems and ultimately fuels all of the Earth's biogeochemical processes (Summons, 1993); therefore, understanding the formation, cycling, and preservation of OC is essential to understanding the cycling of

all bioelements between living and nonliving reservoirs, the formation of economically important petroleum and coal deposits, and predicting how human activity may change the natural balance of these systems.

Much of the OC created during photosynthesis or by chemosynthetic autotrophs is decomposed by heterotrophic organisms. Heterotrophic processes occur in the water column of marine and aquatic environments, as well as in sediments, soils, and rocks. Much of the decomposition of organic matter (OM) occurs under low temperature (<50°C) and pressure during diagenesis. Diagenesis occurs primarily through biological processes (microbes and larger organisms that live in surface sediments) and over depths ranging from microns to hundreds of meters. The OC preserved following diagenesis is subject to further alteration by the processes of catagenesis and metagenesis, which occur at higher temperatures and pressures and lead to the formation of petroleum and natural gas.

Reservoirs

The cycling of OC involves fluxes to and from the major OC reservoirs (Figure 1). Sedimentary rocks are the largest OC reserve, making up approximately 99.5% of the

Carbon (Organic, Cycling), Figure 1 The global organic carbon (OC) cycle, adapted from Hedges (1992). The OC cycle involves fluxes to and from the major surficial and deep reservoirs. Reservoirs are denoted by capital letters, with values in blue. Fluxes due to physical processes (italicized) and primary production (not italicized) are denoted with *arrows*. Flux terms are presented in lower case font, with values given in red. Information presented in this figure is based on published values from Schlesinger (1991), Longhurst (1995), Hedges et al. (1997), Kvenvolden (2002), Richey (2004), IPCC (2007).

total global OC. Despite the relative size of this reservoir, OC only represents one-fifth of the total sedimentary carbon, since inorganic carbon is the dominant fraction (Hedges, 1992). Sedimentary OC occurs primarily as kerogen, coal beds, and petroleum reservoirs, which ultimately come from biogenic processes or sources. Kerogen is an amorphous, highly insoluble particulate OM that is thought to form by two pathways – selective preservation and geopolymerization, both of which occur under low temperature and pressure conditions (Killops and Killops, 2005). Selective preservation involves the formation of kerogen from biomacromolecules that are resistant to microbial degradation. Geopolymerization occurs through a random series of condensation and polymerization reactions involving humic substances. Petroleum is defined as naturally occurring fluid (liquid and gases) that evolves from kerogen. Petroleum is formed primarily from the remains of microbes (algae and bacteria), although some types of petroleum are formed from higher plants. In contrast, coal is a solid and is formed from the remains of higher plants. The most common type of coals, humic coals, is formed through the processes of peatification and coalification, which involve both biological and geochemical processes (Killops and Killops, 2005). The OC in ancient sedimentary rocks provides these economically important fossil fuels as well as a molecular record of life, which has allowed the construction of evolutionary trees and an understanding of the geologic timing of past events and the response of natural systems to tectonic, environmental, and biological change (Brocks and Pearson, 2005). Historically, sedimentary OC affects biologically mediated cycles on geologic time scales, although humans have recently accelerated this cycle through fossil fuel combustion (7.5×10^{15} g C year⁻¹; IPCC, 2007).

The active (surficial) pools of OC include soil humus, land and marine plant tissue, seawater dissolved OC (DOC, <0.5 μ m diameter), and surface marine sediments and gas hydrates (Kvenvolden, 2002; Hedges, 1992). Dead and living particulate OC (>0.5 μ m) are also present in freshwater and seawater pools; however, the DOC pool dominates. With the exception of plant tissue and gas hydrates, most of the active pools of OC are poorly characterized. Terrestrial plant tissue can be further classified as woody biomass (~75%), nonwoody biomass (~15%), and litter (~10%) (Olson et al., 1985). Gas hydrates contain mostly methane and some ethane molecules, and may serve as a large reservoir for OC, although global estimates of the size of this sink are still uncertain (see Kvenvolden, 2002). Soil OM is made up of plant remains (detritus), soil microbes, and humic substances.

Production and fluxes

The major fluxes between organic pools are driven by marine and terrestrial primary production. Photosynthesis, the harvesting of light energy to convert inorganic carbon

to reduced (organic) forms in the tissue of plants, is the primary mode of primary production. However, chemosynthesis by microbial organisms, which uses chemical energy rather than sunlight, is also important. Photosynthesis is carried out by prokaryotes such as cyanobacteria as well as eukaryotic algae and higher plants. The fixation of carbon by plants over the Earth's history accounts for the oxygen in our present atmosphere, thus the cycles of carbon and oxygen are closely linked over geologic time (Hedges, 2002; Hedges and Keil, 1995). In fact, to maintain current atmospheric oxygen levels, rapid cycling of carbon in the surficial pools is required. These pools exchange on relatively short timescales (10^2 – 10^4 years). In contrast, the OC that remains in the sedimentary system cycles slowly (~ 10^8 year; Schlesinger, 1991). Sedimentary reservoirs only become exchangeable through geologic uplift, followed by oxidative weathering of OC by exposure to the atmosphere.

Net global primary production (NPP) on land (45 – 65×10^{15} g C year⁻¹) is dominated by more labile nonwoody plant tissues such as leaves, grasses, and herbaceous annuals (Schlesinger, 1991). The highest gross terrestrial production (82×10^{15} g C year⁻¹) and storage as biomass (56%) occur in the tropics, while polar regions contribute the least (8×10^{15} g C year⁻¹, 0.5%; Taube, 1992). Within these regions, forests are the most productive continental biomes and deserts and tundra are the least (Taube, 1992), reflecting global patterns of temperature and precipitation. Marine primary productivity ($\sim 50 \times 10^{15}$ g C year⁻¹) is dominated by open water (pelagic) phytoplankton productivity because open water constitutes approximately 75% of the total ocean area (Ducklow and McCallister, 2005; Longhurst, 1995). However, when normalized to area, coastal and upwelling areas together account for nearly two thirds of the total oceanic productivity because a greater supply of nutrients is available to support phytoplankton in these areas (Longhurst, 1995). Other primary producers along the coasts (i.e., seagrass, marsh plants, macroalgae, mangroves) are locally important sources of OC.

Delivery of OC (as both dissolved and particulate fractions) from the land to coastal marine environments by rivers accounts for 0.4×10^{15} g C year⁻¹ (Meybeck, 1982; Ittekkot, 1988). However, there remains considerable uncertainty in our ability to adequately quantify carbon exchange from land to the coastal ocean and in our understanding of the processes influencing the fate of terrigenous carbon in coastal sediments (Berner, 1982; Sarmiento and Sundquist, 1992; Hedges and Keil, 1995; Schlünz and Schneider, 2000). Generally, the total annual riverine OC load to the ocean is proportional to the total annual river flow, which is dominated by a small set of rivers that transport the bulk of the fresh water from land to sea (Schlesinger, 1991). However, seasonal and annual/interannual variations in hydrology as well as large events such as storms and hurricanes influence the input, dispersion, and cycling of sediment OM in coastal environments, thus making it difficult to trace terrigenous OM.

In addition, recent molecular and isotopic evidence suggests that OC in seawater and marine sediments is marine, rather than terrestrial, in nature, which suggests that further remineralization of terrestrial material must occur in rivers prior to delivery to the coastal ocean (Schl nz and Schneider, 2000; Richey, 2004; Mayorga et al., 2005) or in the marine environment (Hedges et al., 1997). This is an area requiring further research. Eolian (air) flux from the land to the sea approximates 0.1×10^{15} g C year⁻¹, although this estimate remains uncertain due to methodological difficulties (Romankevich, 1984; Zafiriou et al., 1985).

Decomposition and preservation

Only ~0.1% of global NPP is ultimately preserved within sediments; however, it is this OC that will eventually become part of the sedimentary record and may be transformed into fossil fuels. The remaining 99.9% of global NPP is remineralized to inorganic carbon, nutrients, and water. Remineralization represents a sink for oxygen, linking the global cycles of OC and oxygen. Microfauna, bacteria and fungi (on land) are responsible for the breakdown of OM. Bacterial and fungal decomposition of OM involves a series of steps; macromolecules must first be broken down using extracellular enzymes into dissolved polymers, which are then broken down into low molecular weight monomers (Tissot and Welte, 1984).

The rates and extent of decomposition are influenced by environmental, biological, and physical factors. First, there must be a sufficient supply of labile OM to be degraded. The depth-integrated rate of OM remineralization in marine sediments correlates closely with carbon flux to the sediment surface (Henrichs, 1993). Interestingly, the fraction of OC that is *not* remineralized is also highly correlated with the carbon flux to the sediment surface. Thus, the efficiency of OM decomposition appears to be lower in systems that receive the highest input of OC compared to systems with lower accumulation rates (Henrichs and Reeburgh, 1983). Second, like most metabolic processes, decomposition rates are proportional to temperature, resulting in global patterns of decomposition rates (e.g., higher degradation rates in the tropics than in tundra systems) (Schlesinger, 1991). Oxygen is also a controlling factor for decomposition. Recent evidence suggests that oxygen exposure time, rather than oxygen concentration, may be an important determinant of the extent to which OM is decomposed (Hartnett et al., 1998). OM decomposition occurs under both oxic and anoxic conditions; however, the rates and bacterial communities involved in the processes differ. Oxygen is used preferentially as the terminal electron acceptor during decomposition and results in the most efficient mineralization (i.e., the highest energy yield). Once oxygen is depleted, bacteria utilize other electron acceptors such as sulfate and nitrate. Aerobic decomposition is facilitated

by microbes as well as higher organisms with a range in enzyme capabilities. Anaerobic decomposition is carried out exclusively by microorganisms, and complete remineralization is typically dependent on a consortium of cooperating organisms. Further, anaerobic decomposition processes differ in terrestrial and marine environments because sulfate is abundantly present in marine systems but limited in terrestrial systems. As a result, sulfate reduction is the dominant anaerobic pathway for oxidizing OM in marine systems, while fermentation and methanogenesis dominate in freshwater systems (Henrichs, 1993). The chemical and structural makeup of OM also plays a role in its susceptibility to decomposition (e.g., number of double bonds and functional group composition). For example, nitrogen-rich compounds such as proteins and polynucleotides are usually decomposed preferentially to carbon-rich structural compounds (Wakeham and Canuel, 2006). Additionally, the architecture of the OM may be an important control on its decomposition. Architecture refers to both physical structure (e.g., conformation) as well as OM associations with organic and inorganic matrices (see below).

Decomposition and preservation of OC are closely linked processes, since only OC that is not decomposed is available for preservation, but there are additional factors that may enhance preservation (Burdige, 2007; Wakeham and Canuel, 2006). For instance, the amount of OC that reaches the sediment surface and has the potential to be buried depends in part on productivity in the overlying photic zone and water depth. Sufficiently high productivity is essential for OC to reach the sediment with the potential for preservation (Killops and Killops, 2005). In addition, physical or chemical protection of OM plays a key role in controlling preservation. Protection by binding to inorganic ions, clays, and organic residues decreases the surface area of OM that is exposed to bacteria for degradation. This protection or encapsulation of OM explains why compounds that appear to be labile, or readily available for decomposition, have been found in sedimentary OC deposits. Lastly, the amount of time that OM is exposed to oxic conditions determines the extent to which oxygen-sensitive compounds, compounds that specifically require oxygen for degradation, are preserved (Burdige, 2007).

Preservation of OC occurs predominantly in anoxic marine sediments. More than 80% of preserved OC is located in deltaic-shelf environments associated with fine grain sediments (Bernier, 1982) that support the physical or chemical protection model, since these sediments provide the most potential surface area with which OM can bind. This has likely been true for millions of years, as current petroleum deposits are found in areas that were formerly coastal, fine grained sediments. Major depositional environments include lacustrine environments (open, closed lakes), peat swamps and coal, and continental margins, enclosed or silled basins, and the Black Sea (Killops and Killops, 2005).

Conclusion

The global OC cycle involves exchange of OC between surface and subsurface (buried) reservoirs on time scales of less than one year to millions of years. These fluxes are driven by the production and cycling of OC through biological, physical, and geological processes. The global OC cycle is intimately linked with other global cycles and is sensitive to human-induced perturbations. Humans may have reduced total NPP by up to 40% due to wildfires and pollution, which may be the largest sink for primary production to support a single species in the history of life on the Earth (Vitousek et al., 1986). Fossil fuel combustion and destruction of forests (especially tropical) have decreased the global pool of OC and increased atmospheric carbon dioxide, which has been linked to global climate change. Global atmospheric concentrations of CO₂, methane (CH₄), and nitrous oxide (N₂O) have increased markedly as a result of human activities since preindustrial times (i.e., 1,750). In 2005, concentrations of atmospheric CO₂ (379 ppm) and CH₄ (1,774 ppb) exceeded the natural range over the last 650,000 years (IPCC, 2007). Understanding the changes in the size and composition of the OC reservoir through space and time will help us to better predict the changes in its global cycle as well as the associated cycles of other biologically important elements.

CARBON (ORGANIC, DEGRADATION)

Steven T. Petsch
 University of Massachusetts Amherst, Amherst, MA,
 USA

Synonyms

Carbon biodegradation; Carbon remineralization

Definition

Organic carbon (OC). In geochemistry, carbon that occurs in materials of ultimately biological origin and that can be oxidized. Organic matter (OM) is the material that contains organic carbon (OC).

Degradation. Transformations of OM within the range of temperatures, pressures and environmental conditions found in or near the Earth surface environments. If biological activity is confirmed to cause the transformations, it is termed biodegradation.

Remineralization. Degradation of OM that results in net conversion of OC to inorganic (oxidized) carbon species such as CO_2 or HCO_3^- .

Introduction

The Earth exists in a near balance between photosynthesis and respiration. Photosynthesis, by which inorganic carbon is chemically reduced to biologically-available OC using light energy, generates an estimated 107 Pg C of net new production each year (1 Pg = 10^{15} g), nearly evenly distributed among terrestrial (57 Pg C year⁻¹) and marine (50 Pg C year⁻¹) environments (Field et al., 2007; Sabine et al., 2004). Of this biomass, over 90 Pg C is remineralized each year to inorganic carbon

through aerobic respiration on land and in the oceans, leaving 17 Pg year⁻¹ to be redistributed among different pools of nonliving OM (Field et al., 2007; Sabine et al., 2004). These pools include soils, aquatic and marine sediments, and nonliving OM in the world's oceans. Degradation of organic carbon in these pools balances the crustal carbon cycle, such that total global respiration plus net OC remineralization are believed to match global rates of photosynthesis (Bernier, 2003). Maintaining or slowly shifting this balance has been a critical component of the coupled atmosphere–ocean climate system throughout the Earth's history, and has served to maintain an equable amount of atmospheric oxygen (O_2) for the past 600 million years (Bernier, 1989, 2003).

Degradation of OC in soils

Soils contain complex mixtures of weathered rocks, new minerals formed within soils, and OM. The world's soils contain an estimated 3,200 Pg C (Sabine et al., 2004 and references therein). Much of this OM derives from terrestrial vegetation. As dead vegetation ages within soils, it is degraded by a combination of chemical reactions and biological processes. Soluble components of decaying vegetation may be leached out of soils and relocated by groundwater movement. Organic acids and chelating agents released by plant roots further facilitate the dissolution and hydrolysis of vegetation. Soil macrofauna, especially detritivores such as earthworms, serve to physically mix soil horizons from different depths, moving OM-rich surface leaf litter down to more water- and mineral-rich horizons and reducing the OC and nutrient content of surface soils (Bohlen et al., 2004). Detritivores also accelerate the formation and disintegration of soil carbon aggregates, resulting in overall larger aggregates of fresh (less-degraded) OM mixed to greater depth within soils (Blair et al., 1995; Cortez, 1998). This activity increases soil porosity and permeability, allowing access to oxygen to greater depth in soils to support aerobic respiration processes.

Throughout in the soils, microbial processes both positively and negatively influence soil OM degradation. Fungal hyphae and other microbial exopolymers bind soil carbon and mineral particles together into aggregates. These exopolymers add to the stock of soil OC contributed by terrestrial vegetation, and support mechanisms of physical protection of OM against further degradation; aggregate-bound OM is much less susceptible to degradation than unassociated OM (Baldock and Skjemstad, 2000). Other microorganisms participate in the degradation of soil OM as they obtain energy and cellular carbon through various metabolic processes. While aerobic respiration is confined to shallow depths of the soil where O_2 can penetrate, anaerobic processes extend throughout the soil profile, from O_2 -free microenvironments within surface soils to deeper O_2 -free soils and weathered regolith.

Soil OC degradation is limited by the availability and reactivity of both OM and electron acceptors that fuel anaerobic respiration. Sulfate is not an abundant

Introduction

The Earth exists in a near balance between photosynthesis and respiration. Photosynthesis, by which inorganic carbon is chemically reduced to biologically-available OC using light energy, generates an estimated 107 Pg C of net new production each year (1 Pg = 10^{15} g), nearly evenly distributed among terrestrial (57 Pg C year⁻¹) and marine (50 Pg C year⁻¹) environments (Field et al., 2007; Sabine et al., 2004). Of this biomass, over 90 Pg C is remineralized each year to inorganic carbon

through aerobic respiration on land and in the oceans, leaving 17 Pg year⁻¹ to be redistributed among different pools of nonliving OM (Field et al., 2007; Sabine et al., 2004). These pools include soils, aquatic and marine sediments, and nonliving OM in the world's oceans. Degradation of organic carbon in these pools balances the crustal carbon cycle, such that total global respiration plus net OC remineralization are believed to match global rates of photosynthesis (Bernier, 2003). Maintaining or slowly shifting this balance has been a critical component of the coupled atmosphere–ocean climate system throughout the Earth's history, and has served to maintain an equable amount of atmospheric oxygen (O_2) for the past 600 million years (Bernier, 1989, 2003).

Degradation of OC in soils

Soils contain complex mixtures of weathered rocks, new minerals formed within soils, and OM. The world's soils contain an estimated 3,200 Pg C (Sabine et al., 2004 and references therein). Much of this OM derives from terrestrial vegetation. As dead vegetation ages within soils, it is degraded by a combination of chemical reactions and biological processes. Soluble components of decaying vegetation may be leached out of soils and relocated by groundwater movement. Organic acids and chelating agents released by plant roots further facilitate the dissolution and hydrolysis of vegetation. Soil macrofauna, especially detritivores such as earthworms, serve to physically mix soil horizons from different depths, moving OM-rich surface leaf litter down to more water- and mineral-rich horizons and reducing the OC and nutrient content of surface soils (Bohlen et al., 2004). Detritivores also accelerate the formation and disintegration of soil carbon aggregates, resulting in overall larger aggregates of fresh (less-degraded) OM mixed to greater depth within soils (Blair et al., 1995; Cortez, 1998). This activity increases soil porosity and permeability, allowing access to oxygen to greater depth in soils to support aerobic respiration processes.

Throughout in the soils, microbial processes both positively and negatively influence soil OM degradation. Fungal hyphae and other microbial exopolymers bind soil carbon and mineral particles together into aggregates. These exopolymers add to the stock of soil OC contributed by terrestrial vegetation, and support mechanisms of physical protection of OM against further degradation; aggregate-bound OM is much less susceptible to degradation than unassociated OM (Baldock and Skjemstad, 2000). Other microorganisms participate in the degradation of soil OM as they obtain energy and cellular carbon through various metabolic processes. While aerobic respiration is confined to shallow depths of the soil where O_2 can penetrate, anaerobic processes extend throughout the soil profile, from O_2 -free microenvironments within surface soils to deeper O_2 -free soils and weathered regolith.

Soil OC degradation is limited by the availability and reactivity of both OM and electron acceptors that fuel anaerobic respiration. Sulfate is not an abundant

electron acceptor in most soils, while ferric iron and nitrate can be. Soil OM is also susceptible to degradation other than respiration. Fermentative degradation of soil OM breaks down terrestrial inputs and biopolymers into small molecules including low molecular weight organic acids, alcohols, and sugar monomers. Methanogenesis too is an important mechanism of OC degradation in soils, consuming fermentation products of such as methanol, H_2 , and acetate, sustaining the fermentative breakdown of soil OM.

Many components of soil OM are fairly susceptible to degradation and do not persist in soil environments. These include carbohydrate biopolymers (e.g., cellulose, chitin, and other polysaccharides), proteins, and nucleic acids. Other components such as lipids, lignin, and black carbon are much more resistant to degradation, and can persist for millennia as intact compounds or transitional degradation products in soils (Derenne and Largeau, 2001). Lipids commonly found preserved in soils include highly aliphatic waxes, free hydrocarbons such as *n*-alkanes and isoprenoids, and biopolymers such as cutan and suberan. Lignin is a structural biopolymer in plant cell walls that derives from condensation of phenolic precursors. Black carbon comprises a broad suite of aromatic and graphitized organic materials that form during incomplete combustion of terrestrial biomass or fossil fuels; these materials are believed to be extremely resistant to degradation (Schmidt and Noack, 2000). During degradation in soils, soil OM components are remineralized at rates depending on a complex combination of intrinsic reactivity (polymeric material being more resistant than individual monomers), physical protection, (inside mineral aggregates or encapsulated within more resistant biopolymers) and lability (proteins, nucleic acids, and carbohydrates being more reactive than lipids and lignin).

Degradation of OC in the oceans

OC occurs in both dissolved and particulate forms in the oceans. Approximately $50 \text{ Pg C year}^{-1}$ derives from marine primary production driven by phytoplankton (Field et al., 2007; Sabine et al., 2004 and references therein). Rivers deliver an estimated 0.5 Pg of OC to the oceans each year. Primary production is confined to the photic zone of the world ocean, where light and nutrients combine in sufficient abundance to support photosynthetic activity. Within and immediately below the photic zone is a zone of intense heterotrophic activity, in which grazing zooplankton and aerobic heterotrophic bacteria consume particulate OM (Lee et al., 2004). The heterotrophic activity in near-surface waters has several impacts on OC degradation in the oceans. One is that $>90\%$ of primary production is effectively remineralized in the upper 200 m of the marine water column, leaving only a small fraction of surface particulate OM for export to the deep ocean (Suess, 1980; Honjo et al., 2008). Second is that mineral ballasting (association of OM with biogenic minerals produced by plankton or with minerals delivered

from continents to the surface ocean by winds and river) increases the sinking rate of OM through the water column, reducing the time available for degradation in the ocean (Lee et al., 2004; Armstrong et al., 2002). Aggregation of particulates in surface waters results in increased particle size and sinking velocity, further accelerating the export of less-degraded particulate OM to a depth (Sheridan et al., 2002). Lastly, heterotrophic grazing of surface particulates results in net evolution of the composition of sinking particulates, as more labile or easily degraded components are consumed (Lee et al., 2004; Wakeham et al., 1997).

In living biomass of the photic zone, OM that can be identified at the molecular level comprises $>80\%$ of total OC. Between 200 and 1,000 m water depth, molecularly uncharacterized material comes to dominate total OM, such that much of the material delivered to seafloor sediments cannot be assigned to typical compound classes such as lipids, carbohydrates, and amino acids (Lee et al., 2004). Some of this relative increase in uncharacterized material may result from selective preservation of photic zone precursors, while some may be added to sinking particulates as exopolymeric material generated by heterotrophic bacteria that feed on sinking particulate matter. There are also changes observed in the molecularly characterizable fraction of sinking particulate OM. Lipids resistant to degradation, such as long-chain saturated fatty acids and alkenones, are substantially enriched in relative abundance compared with initial photic zone biomass, while pigments, many carbohydrates, and polyunsaturated fatty acids are readily lost from particulates within or below the photic zone (Lee et al., 2004).

This background picture of OC degradation is confounded by the role of mineral surfaces. Minerals, whether delivered to surface waters from the continents by winds and rivers, or produced by plankton in the water column, make up the bulk of sinking particulate mass. OM can be sorbed to mineral particles, and with their greater density, OM-associated particulates can sink rapidly through the water column, helping to export relatively undegraded OC beyond the photic zone. In this way, terrestrially derived OM, which may be protected from degradation by association with detrital minerals or OM macromolecules, can be delivered to deep sea sediments. More generally, marine OM may be protected from degradation by adsorption in mesopores of sinking mineral particles, or OM mineral aggregates taken together may resist degradation, where OM is located in interstices between the mineral grains (Hedges et al., 2001). Clearly, degradation of OM within the marine water column reflects a complex interplay of inherent resistance of various organic materials across a continuum of lability, coupled with mechanisms of both speeding the rate of sinking through the water column and increasing protection from degradation by the association of OM with biogenic and terrigenous minerals.

This discussion of heterotrophic degradation of OC applies to an oxygenated water column. In several locations around the globe, large proportions of the water column are

anoxic. These include the Black Sea, the Cariaco Basin, and seasonally in the Arabian Sea, eastern tropical North Pacific and California Borderlands Basins, among others. Lack of oxygen effectively shuts down aerobic respiration in these regions, allowing the roles of anaerobic microbial processes to dominate OC degradation. In these anoxic basins, the extents of OM degradation as a fraction of primary production are lower than in open ocean sites, leading to higher sediment OC contents. Although the rates of degradation under oxic and anoxic conditions may be similar, the overall proportion of total OM that resists degradation may be greater under anoxic conditions (Van Mooy et al., 2002).

Degradation of OC in marine sediments

Efficient heterotrophic processes in the water column mean that only a small fraction ($<1\%$) of primary production reaches the sea floor. Of this, most is degraded within the upper meters of sediment, leading to OC burial of approximately $160 \text{ Tg C year}^{-1}$ (Berner, 1989; Hedges and Keil, 1995). Clearly, a large fraction of ocean carbon inputs ($\sim 50 \text{ Pg C year}^{-1}$) is degraded in both the water column and shallow sediments.

There is a positive relationship between sediment accumulation rate (either cm year^{-1} or $\text{g}_{\text{carbon}} \text{ cm}^{-2} \text{ year}^{-1}$) and OC burial efficiency, where burial efficiency is the fraction of OC ultimately preserved at depth in sediment relative to OC delivered to the sediment-water interface (Burdige, 2007; Aller, 1998; Canfield, 1994). At very low sedimentation rates, the sediment layers are buried very slowly, and aerobic processes have ample time to remineralize the OM that is delivered to these sediments, thereby explaining the low total OC contents of many low sedimentation rate marine settings. Closer to shore as sedimentation rates increase, rapid burial means that anoxic conditions dominate at shallower sediment depths, and anaerobic degradation processes become more important. Nonetheless, sediments underlying oxygen-deficient waters do not uniformly exhibit high carbon burial efficiency, indicating that oxygen alone is not the primary driver controlling OM degradation rates (Burdige, 2007). Burial efficiencies among a range of marine sediment types range between 10% and 20%. Thus, very little primary production escapes degradation processes to become incorporated into the sedimentary record.

Controls on OC degradation in sediment are similar to those operating in soils and in the marine water column: selective degradation of inherently resistant components, physical protection through association with mineral or organic polymeric surfaces, and availability of electron acceptors and/or appropriate substrates for nonrespiration degradation processes such as fermentation and methanogenesis (Burdige, 2007). Oxygen does not limit OC degradation. Most marine sediments are anoxic within centimeters of the sediment–water interface. Denitrification, sulfate-, iron- and manganese-reduction, fermentation, and methanogenesis are all active components of OM degradation. Oxygen exposure time is nonetheless

a useful proxy for understanding the extent of OC degradation from one environment to the other. Longer cumulative oxygen exposure times result in more OC degradation in sediment and overall lower OM burial efficiency (Aller, 1998; Hartnett et al., 1998).

Most OC is buried in shallow, continental margin sediments. These environments have been targets of numerous investigations over the years, and have provided insights into OC degradation processes in the uppermost few meters of buried sediments (see Martens et al., 1992). Deeply buried marine sediment such as from the Woodlark Basin and Peru Margin in turn demonstrate microbial activity hundreds of meters deep in sediments, indicating OC degradation can persist at slow rates for geologic spans of time (D'Hondt et al., 2004; Wellsbury et al., 2002).

Degradation of OC in ancient sedimentary rocks

The single largest pool of OC on the Earth (15 million Pg C) is represented by OM contained in ancient sedimentary rocks, a mass that dwarfs all other pools of OC combined (Field et al., 2007; Sabine et al., 2004). Traditionally, OC in sedimentary rocks has been viewed as resistant to degradation other than high temperature oil and gas generation or graphitization. Degradation can occur where sedimentary rocks are exposed at the Earth's surface through erosion and soil formation (Petsch et al., 2000, 2001). One unexpected theme emerging from this work is that OC degradation during rock weathering is not completely efficient. Highly aged OC is detected in river particulates from watersheds draining sedimentary lithologies (Longworth et al., 2007; Goni et al., 2005; Blair et al., 2003; Leithold et al., 2006).

However, very little of the total pool of sedimentary OM is exposed in the Earth surface environments; most remains deeply buried in the Earth's crust for millions of years. The persistence of OC in sedimentary rocks for long expanses of geologic time, and its preservation up to the present day, would suggest that degradation processes must largely cease after the burial of OM in sediments. Yet, microbial degradation of deeply buried OM has been described in a number of subsurface environments. These include clear signatures of hydrocarbon biodegradation in many petroleum systems (Head et al., 2003, 2006; Jones et al., 2008) and OM-rich sedimentary rocks (Formolo et al., 2008), coupled with molecular biological analyses that support an interpretation of an active subsurface biosphere involved in OC degradation (Waldron et al., 2007; Jones et al., 2008). These subsurface OC degradation processes are particularly valued for their role in natural gas generation in petroleum systems and other sedimentary basins.

Summary

OC degradation represents the suite of processes by which OM is transformed and remineralized, mainly through biological activity, within soils, aquatic systems,

sediments, and sedimentary rocks. The diverse forms and compositions of natural OM result in a wide range of rates of degradation, as some components are inherently resistant to degradation while others are labile and are thus quickly consumed following biosynthesis. The inherent resistance of some components of OM results in selective preservation in soils and sediments. This selective preservation is attenuated by mechanisms of physical protection, either by association with mineral surface or encapsulation of labile components within more recalcitrant organic matrices. In this way, nominally labile OC can be preserved for greater extents of time or transported across longer distances than would otherwise be the case. Future investigations of OC degradation will likely focus on (1) improved construction of carbon budgets for soils, the oceans, and sediments; (2) the mechanism(s) by which certain compound classes and organic materials remain resistant to biological degradation; (3) improved understanding of the association of organic materials with mineral surfaces, their selective adsorption/desorption behavior, and the physical scale of these relationships; (4) the roles that terrestrial inputs of OM to marine sediments and recycling of ancient OM during rock weathering play in controlling the overall reactivity and preservation of OC in sediments; and (5) improved understanding of couplings between OM composition and degradation processes active within deep subsurface sedimentary environments.

CARBONATE ENVIRONMENTS

Eberhard Gischler

J.W. Goethe-Universität, Frankfurt am Main, Germany

Definition

Carbonate environments occur both in the terrestrial and marine realms as well as in transitional zones between the land and the sea. The variety of environments spans from high-elevation continental lakes to the deep sea, from the equator to latitudes of about 60°, and they include dry and wet climate realms. The majority of carbonates are produced in the sea, currently in more or less similar proportions in neritic and pelagic settings. Carbonate production is to a large part a consequence of biological activity, either directly as in shell and skeleton formation or indirectly as a result of metabolic reactions, which trigger precipitation. The highest rates of carbonate production per unit time and space are probably reached in tropical coral reefs where several kilograms of calcium carbonate form on 1 m² during 1 year's time.

Introduction

Modern carbonate sediments are largely a product of biologic activity, either enzymatically controlled like in calcium carbonate (CaCO₃) shell and skeleton formation of aquatic organisms or indirectly by the metabolic activity

C

CALCAREOUS ALGAE

The term “calcareous algae” refers to various kinds of benthic and planktonic algae whose thalli contain biochemically precipitated calcium carbonate (CaCO_3) as skeletal material (Wray, 1977; Braga and Riding, 2005). Precipitation of CaCO_3 (as calcite and/or aragonite) may occur within or on the algal bodies. The term may also include mechanically accreted deposits of calcium carbonate caused by algae, usually as an interaction of biological and physical processes. Calcareous algae are a highly artificial group that constitutes calcifying members of the Chlorophyta (green algae), Rhodophyta (red algae), and Phaeophyta (brown algae) and is sometimes also used for Cyanobacteria. At present, calcareous algae are one of the most important reef builders (see “[Carbonate Environments](#)”). For a detailed reading, please refer to “[Algae \(Eukaryotic\)](#).”

Definition

Cyanobacteria are alga-like bacteria that can perform oxygenic photosynthesis and nitrogen fixation (Whitton and Potts, 2000; Herrero and Flores, 2008). They have a long history and are diverse and widespread in marine, freshwater, and terrestrial environments at the present-day, where they are key primary producers in both microbial mat and planktic ecosystems. As the initiators of plastids, they have played a fundamental role in algal and plant evolution (Raven, 2002). Cyanobacteria occupy benthic substrates and can also drift in the water column. Their photosynthetic uptake of inorganic carbon can stimulate CaCO_3 precipitation. This calcification can produce filamentous microfossils in benthic mats that are preserved as stromatolites and thrombolites, and can also cause water column precipitation of carbonate mud that settles to lake and sea floors.

Introduction

However, cyanobacterial calcification is not obligatory and is directly dependent on environmental conditions. This accounts for apparent discrepancies between the geological ranges of organic-walled and calcified cyanobacterial fossils. Calcified cyanobacteria have not been recognized in marine sediments older than ~1200 Ma ago (Kah and Riding, 2007), whereas there is evidence that cyanobacteria appeared in the late Archaean or Palaeoproterozoic, in the range ~2900–2150 Ma ago (Cavalier-Smith et al., 2006; Hofmann, 1976). This mid-Proterozoic appearance of sheath-calcified cyanobacteria is thought to reflect the development of CO_2 -concentrating

mechanisms (CCMs) as atmospheric CO₂ levels declined (Riding, 2006). Calcified cyanobacterial fossils remained conspicuous components of marine stromatolites and thrombolites through much of the Neoproterozoic, Palaeozoic, and Mesozoic, but became vanishingly scarce in the Cenozoic, including present-day seas (Riding, 1982), probably due to decline in seawater saturation for CaCO₃ minerals (Riding, 1993, p. 514; 2000, p. 200; Kempe and Kazmierczak, 1994). Cyanobacterial calcification is thus a good example of “induced,” as opposed to “controlled” biocalcification. Its close environmental dependence can be used to interpret changes in past conditions such as carbonate saturation state and the availability of inorganic carbon for photosynthesis. In addition to their sedimentological importance, calcified cyanobacteria can therefore assist in the reconstruction of seawater chemistry and atmospheric composition over long geological time scales.

Controls on calcification

The ability of cyanobacteria to grow and reproduce whether they are calcified or uncalcified illustrates the non-obligate nature of their calcification (Pentecost and Riding, 1986). Two factors that directly influence cyanobacterial calcification are the saturation state of ambient waters and the mechanism of photosynthetic uptake of inorganic carbon (Riding, 2006).

Carbonate saturation state: Cyanobacterial calcification requires waters in which CaCO₃ precipitation is thermodynamically favored (Pentecost, 1981; Kempe and Kazmierczak, 1994; Merz-Preiß and Riding, 1999). It has been very common in marine environments at times since the Neoproterozoic, but these episodes are markedly episodic and can be interspersed by long periods when cyanobacterial calcification is scarce (Riding, 1992). Cyanobacterial sheath calcification has not been confidently recognized in present-day marine environments, and is rare to absent throughout the Cenozoic (Riding, 1982; Arp et al., 2001). In contrast, cyanobacterial calcification is locally well-developed in present-day calcareous streams and lakes, and is often significantly involved in the formation of tufa and oncoids (Golubic, 1973; Pedley, 1990; Pentecost, 2005). In streams, calcification reflects increased saturation state that results from warming and degassing of spring waters, especially in turbulent zones, together with the stimulus of photosynthetic carbon removal (Merz-Preiß and Riding, 1999; Bissett et al., 2008). In lakes, precipitation is stimulated by seasonal warming as well as the activity of phytoplankton blooms that include cyanobacteria (Kelts et al., 1978; Thompson and Ferris, 1990). These present-day environments are vulnerable to pollutants such as agricultural fertilizers. Cyanobacterial calcification has declined over the past century in temperate climate hardwater streams and lakes of Europe and North America, largely in response to these anthropogenic changes (Pentecost, 2005, pp. 283–287),

among which phosphate inhibition of CaCO₃ precipitation (Raistrick, 1949) may be important (Hägele et al., 2006).

CO₂-concentrating mechanisms: Photosynthetic carbon uptake can directly influence cyanobacterial calcification. Diffusive entry of CO₂ into the cell may not significantly affect ambient pH, but active bicarbonate uptake increases pH near the cell (Miller and Colman, 1980) that promotes calcification (Thompson and Ferris, 1990). Bicarbonate (HCO₃[−]) is actively transported into the cell and intracellularly converted to CO₂ for photosynthesis. These processes lead to increased pH in the immediate vicinity of the cell. Where ambient waters are sufficiently saturated for CaCO₃ minerals then this localized pH increase can trigger the nucleation of CaCO₃ crystallites on or near the cell surface or in the enveloping mucilaginous sheath (Figures 1 and 2):

Active bicarbonate uptake and its conversion within the cell to CO₂ by carbonic anhydrase are adaptations to reduced availability of CO₂. They constitute CCMs (Kaplan and Reinhold, 1999). CCM induction can be triggered by localized carbon limitation, e.g., within microbial mats or phytoplankton blooms, and also by fall in global atmospheric CO₂ levels. Modeled estimates suggest that atmospheric CO₂ has fluctuated widely during the Phanerozoic, up to levels that are 25 or more times higher than present atmospheric level (PAL) (Berner and Kothavala, 2001). CCMs are well-developed in cyanobacteria (Kaplan et al., 1980; Giordano et al., 2005) and experiments suggest that they are induced when ambient CO₂ falls below a critical threshold that is roughly equivalent to 10 PAL (Badger et al., 2002). It therefore seems likely that CCM induction plays a significant role in cyanobacterial calcification (Thompson and Ferris, 1990; Merz, 1992), especially at times in the geological past when CO₂ levels have been below 10 PAL (Riding, 2006, p. 302).

Sites of calcification

Calcification in cyanobacteria is close, but external, to the cell. CaCO₃ crystals nucleate either within the protective mucilaginous sheath, or on or close to the cell surface (Thompson and Ferris, 1990; Merz, 1992). Sheath impregnation by crystallites (Figure 1) can produce coherent tubular and shrub-like calcified structures that preserve the sheath morphology and can be preserved as microfossils for hundreds of millions of years (Riding, 1991). In contrast, if isolated crystals form near the cell surface, they do not form a preservable shape but can be released as allochthonous particles (“whittings”) (Figure 2). These can accumulate as masses of micron-size carbonate mud sediment on lake and sea floors and can also survive as ancient geological deposits. However, they are not known to possess features that distinguish them as

Calcified Cyanobacteria, Figure 1 Model of in vivo sheath calcification in a filamentous cyanobacterium related to CO_2 -concentrating mechanism (CCM)-enhanced photosynthesis (based on information in Riding, 2006, Fig. 3). The CCMs involve active carbon transport into the cell and conversions that liberate OH^- ions. Calcification is stimulated by photosynthetic carbon uptake and OH^- release which elevates sheath pH. If ambient carbonate saturation is already elevated, with raised pH, extracellular HCO_3^- converts into CO_3^{2-} , further increasing saturation state that promotes CaCO_3 nucleation in the sheath.

Calcified Cyanobacteria, Figure 2 Model of in vivo sheath calcification in a picoplanktic coccoid cyanobacterium related to CCM-enhanced photosynthesis (based on information in Riding, 2006, Fig. 3). The CaCO_3 nucleation (blue diamonds) occurs on and near the cell surface. The crystals can ultimately be sedimented to the lake or sea floor as carbonate mud.

cyanobacterially induced precipitates, and cannot at present be differentiated from carbonate mud of other origins.

Sheath calcification: The protective mucilaginous sheath that envelops benthic calcified cyanobacteria provides a diffusion limited site that enhances the pH rise resulting from carbon uptake (Figures 3 and 4). The sheath is a structured form of EPS (Drews and Weckesser, 1982) providing support, stability, and protection against physical damage, dehydration, and grazers (Dudman, 1977). It can contain the pigment scytonemin that acts as a barrier to ultraviolet radiation (Garcia-Pichel and Castenholz, 1991; Proteau et al., 1993; Dillon and Castenholz, 1999), binds nutrients and metals (Yee et al., 2004), and facilitates gliding motility (Stal, 1995, p. 4; Hoiczky, 1998). Sheath calcification can be partial or complete, and can be limited to the sheath interior (sheath impregnation) or form an external crust (sheath encrustation) (Riding, 1977). For example, it can occur as isolated crystals (Pentecost, 1987, Fig. 1d), form a crystalline network (e.g., Friedmann, 1979, Fig. 9), or create a relatively solid tube of closely juxtaposed crystals (e.g., Couté and Bury, 1988, pl. 2).

Although saturation state with respect to carbonate minerals and CCM induction appear to be key controls on cyanobacterial sheath calcification over geological timescales (Riding, 2006), differences in degree of calcification between different species/strains of cyanobacteria in the same environment also indicate taxonomic specificity for calcification (Golubic, 1973; Merz, 1992; Défarge et al., 1994). Further research is required to elucidate the extent to which such specificity may reflect differences in sheath structure and sheath development, CCM induction, or other factors.

Calcified Cyanobacteria, Figure 3 *Girvanella*, calcified cyanobacterial sheath, early mid-Ordovician, Lunnan, Tarim, China. Width of view 1 mm. Thin-section courtesy Jia-Song Fan.

Calcified Cyanobacteria, Figure 4 Thin-section of present-day oncoid microfabric showing calcified shrub-like sheath surrounding space left by the strand of cells (trichome, arrowed). The cyanobacterium is thought to be the oscillatoriacean *Schizothrix calcicola*, and the calcified sheath closely resembles the microfossil *Angulocellularia* (also *Angusticellularia*), which is locally common in Cambro-Ordovician reefs (Riding and Voronova, 1982). Squaw Island, Canandaigua Lake, New York State, USA.

In addition to in vivo sheath calcification, postmortem sheath degradation by heterotrophic bacteria can result in partial external calcification (Chafetz and Buczynski, 1992), although in culture experiments this may in part be related to the growth medium used (Arp et al., 2002). This incomplete and irregular calcification of decomposing sheaths contrasts with sheath impregnation that produces well-defined tubiform fossils such as *Girvanella* in which wall-thickness remains constant in individual specimens (Riding, 1977, 2006).

Biogenic whiting precipitation: In contrast with relatively large and distinct calcified fossils, such as *Girvanella*, that result from sheath calcification, CaCO_3 precipitates associated with coccoid cyanobacterial blooms are most noticeable as “whittings”. These are ephemeral milk-white patches in freshwater calcareous lakes and shallow tropical seas formed by dense masses of suspended small CaCO_3 crystals (Cloud, 1962). Whiting is a descriptive term, and all whittings are not necessarily biogenic. In addition to the triggering effect of phytoplankton photosynthesis, they could reflect essentially abiogenic CaCO_3 crystal nucleation in the water column, and also – in very shallow water – bottom mud re-suspended by currents or fish (Shinn et al., 1989).

Biogenic cyanobacterial whittings are documented by studies of seasonal blooms of unicellular picoplanktic (cell size in range 0.2–2 μm) cyanobacteria, such as *Synechococcus*. These benefit from efficient CCMs (Badger and Price, 2003) where dissolved inorganic carbon (DIC) availability is limited, as under bloom conditions (Rost et al., 2003). Together with diatoms and other planktic algae, *Synechococcus* is implicated in stimulating biogenic whiting precipitation in present-day freshwater calcareous oligotrophic lakes (Thompson and Ferris, 1990; Dittrich et al., 2004; Lee et al., 2004). Since a sheath is lacking in picoplankton such as *Synechococcus*, calcification is instead localized on a paracrystalline surface layer that provides a binding site (Thompson, 2000, p. 253). This surface layer can be shed, producing biogenic whiting crystals that are deposited from suspension, either individually or as poorly structured aggregates along with organic cells, on lake beds.

In addition to lakes, picoplanktic cyanobacteria are widespread in the open ocean and in nearshore marine environments. They form blooms in Florida Bay, and marine strains of *Synechococcus* calcify under experimental conditions (Lee et al., 2004). There has been much debate concerning whether marine whittings in shallow tropical seas, such as the Bahama Banks, have a similar origin to those in temperate calcareous lakes, and could therefore potentially account for abundant lime mud production on ancient carbonate platforms. If marine whittings on the Bahama Banks are water column precipitates, then they would be important sources of carbonate mud and could be triggered by planktic cyanobacteria (Robbins and Blackwelder, 1992; Robbins et al., 1997). However, CaCO_3 precipitation in freshwater lakes is favored by low pH buffering, whereas in present-day seawater buffering limits pH fluctuation, thereby reducing the response to photosynthetic removal of CO_2 and HCO_3^- . Several studies have suggested that Great Bahama Bank whittings are not due to water column precipitation (Broecker and Takahashi, 1966; Morse et al., 1984; Broecker et al., 2000). For example, whiting CaCO_3 has a $^{14}\text{C}/^{12}\text{C}$ ratio that differs from that of inorganic carbon in the whiting water, but is similar to that of the seafloor sediment. In addition, the saturation state of Bahama Bank waters appears to be too low for pseudohomogeneous precipitation of CaCO_3 .

(Broecker et al., 2001, p. 591; Morse et al., 2003). Broecker et al. (2000) concluded that resuspension of sediment is the dominant process involved in marine whittings on the Bahama Banks. Further work is required to resolve this question, but present-day seawater saturation state in general may be too low to permit CaCO_3 nucleation even within blooms of picoplankton that are operating CCMs.

Nonetheless, biogenic whittings may have occurred under different conditions of seawater chemistry in the geological past, and could therefore have been important sources of fine-grained carbonate. Within plankton blooms, photosynthetic uptake can significantly deplete pCO_2 (Riebesell et al., 1993; Rost et al., 2003), and it is likely that selective pressure for picoplankton to induce CCMs first developed under bloom conditions.

Fossil calcified cyanobacteria

Calcified cyanobacterial fossils have long been noticed in limestones, although they have often been confused with other organisms. Sheath calcified cyanobacteria are morphologically simple fossils, mainly with the appearance of shrub-like dendritic masses (Figure 4) and tangled or erect, sometimes radially arranged, tubes (Figure 3). Densely micritic branched filaments such as *Epiphyton*, and chambered clusters such as *Renalcis* have also often been regarded as possible calcified cyanobacteria. At the same time, because of their general lack of distinguishing features, many of these fossils have often also been compared with calcified green and red algae, and also with foraminifers and sponges. For example, when Nicholson and Etheridge (1878) named *Girvanella* they compared it with foraminifers, and it has subsequently variously been regarded as a calcareous sponge (Seely, 1885), green alga (Rothpletz, 1891), and red alga (Korde, 1973). Bornemann (1886) recognized its cyanobacterial nature, and Pollock (1918) identified it as a calcified sheath. Individual calcified cyanobacteria are normally microscopic, but they commonly form much larger aggregates that are significant components of stromatolites, oncoids, thrombolites, dendrolites, reef crusts, and freshwater tufa deposits that range up to decametric in size.

Three main morphological groups can be distinguished (Riding, 1991): tubes, dendritic shrubs and filaments, and hollow chambers.

Tubes: *Girvanella*, originally described from the Middle Ordovician of Scotland, is very simple: unbranched, often irregularly tangled, tubular filaments of uniform diameter, usually <50 microns, and a thin wall of even thickness (Figure 3). Similar tubes, but often organized into cable-like strands, include *Batinivia*, *Botominella*, *Cladogirvanella*, *Razumovskia*, and *Subtifloria*. *Obruchevella* is coiled. *Ortonella* was described from the Mississippian of England (Garwood, 1914) where it forms oncoids (spherical stromatolite nodules) and stromatolitic crusts. It consists of tubes similar in size to those of *Girvanella*, but distinguished by being erect and branched. Somewhat similar forms include *Bajanophyton*,

Bija, *Botomaella*, *Cayeuxia*, and *Hedstroemia*. Pia (1927, pp. 36–40) recognized that very small tubiform fossils such as *Girvanella* and *Ortonella* were cyanobacteria when he placed them in a new group, the Porostromata.

Dendritic shrubs and filaments: *Angusticellularia* (also named *Angulocellularia*) described from the Cambrian of Siberia by Vologdin (1962) is a submillimetric vertically orientated and irregularly dendritic shrub-like mass of dense micrite (Figure 4). In contrast, narrow branched micritic filaments, usually not tubiform but in some cases with light-colored transverse bands, comprise a group that includes *Epiphyton*, originally described from the Cambrian of Sardinia by Bornemann (1886), and among others, *Epiphytonoides*, *Gordonophyton*, and *Tubomorphophyton*.

Hollow chambers: *Renalcis*, described from the Cambrian of southern Siberia by Vologdin (1932), is a hollow thick-walled chambered microfossil that typically forms irregular submillimetric clusters. Broadly similar fossils, such as *Izhella* and *Shuguria*, are distinguished by wall thickness and number of chambers. Some form millimetric dendritic growths. *Chabakovia* filaments consist of thin-walled chambers. In contrast, *Gemma* and *Tarthina* have few chambers with very thick walls.

There is considerable mingling of characters among some of these generally simply organized fossils that can make them difficult to distinguish within these broad groups (Pratt, 1984; Riding and Voronova, 1985; Woo et al., 2008). Dense filaments and chambered forms are much more problematic, whereas tubiform and shrub-like forms can often be compared with present-day sheath calcified cyanobacteria. These include sedimentologically important Cambrian and late Devonian fossils such as *Epiphyton* and *Renalcis* that have some resemblances to cyanobacteria but are not identical to modern examples, and are generally referred to as calcimicrobes. Some *Epiphyton* closely resemble red algae (Luchinina and Terleev, 2008).

Proterozoic record and secular controls

The possibilities that marine carbonate saturation state and changes in atmospheric CO_2 level could be reflected in the geological record of cyanobacterial calcified microfossils and carbonate mud (Riding, 2006, p. 309) focuses attention on the mid-Proterozoic interval when calcified sheaths first appeared (Kah and Riding, 2007) and carbonate mud became abundant (Sherman et al., 2000, p. 290) (Figure 5).

CCM induction

Badger et al. (2002) suggested that cyanobacterial CCMs developed in the late Palaeozoic as CO_2 declined and O_2 increased. However, both modeling and palaeosol proxies (Kasting, 1987; Sheldon, 2006) suggest that similar decline in CO_2 occurred in the mid-Proterozoic. It can therefore be suggested that the Mesoproterozoic appearance of calcified sheath microfossils reflects development of CCMs as CO_2 fell below a critical threshold that may

Calcified Cyanobacteria, Figure 5 Increase in marine carbonate mud accumulation ~ 1400 – 1300 Ma ago (Sherman et al., 2000) and first appearance of sheath-calcified cyanobacteria ~ 1200 Ma ago (Kah and Riding, 2007) compared with decline in estimated atmospheric CO_2 values. It is suggested that decline in CO_2 to $\sim 10\times$ present atmospheric level favored development of CCMs that promoted cyanobacterial sheath calcification and whiting production (Riding, 2006). Incorporation of calcified filaments in microbial carbonates gave rise to calcified microbe thrombolites and dendrolites. Inferred Proterozoic CO_2 trend based on Sheldon (2006), Kah and Riding (2007), Hyde et al. (2000), and Ridgwell et al. (2003). Phanerozoic CO_2 trend from Berner and Kothavala (2001, Fig. 13). Threshold for CCMs based on Badger et al. (2002). Decline in CO_2 level below $10\times$ present-level was repeated ~ 350 Ma ago and coincides with marked Devonian-Mississippian increase in calcified cyanobacteria (see Arp et al., 2001, Figs. 3d and 8b).

have been $\sim 10\times$ PAL (Badger et al., 2002; Riding, 2006; Kah and Riding, 2007). Under high early Proterozoic CO_2 levels, cyanobacterial photosynthesis may have relied on CO_2 diffusion that may not have significantly altered pH near the cell surface. Falling CO_2 levels would have encouraged active carbon uptake to maintain photosynthesis and this, in turn, promoted calcification (Figures 1 and 5).

Carbonate mud: Carbonate mud appears to have been scarce in the late Archaean (Sumner and Grotzinger, 2004), but it increased in abundance during the Proterozoic (Kah and Grotzinger, 1992) and was widespread in the Neoproterozoic (Herrington and Fairchild, 1989). Much of it is thought to have been produced by whittings stimulated by phytoplankton photosynthesis (Grotzinger, 1989, 1990). A significant increase in carbonate mud occurred ~ 1400 – 1300 Ma ago (Sherman et al., 2000, p. 290), prior to the appearance of sheath calcification (Kah and Riding, 2007). This “water column factory” transformed carbonate platform sedimentation by creating extensive micrite-rich subtidal deposits (Sherman et al., 2000, p. 290). The timing of this increase in carbonate mud therefore broadly coincided with the first appearance of *Girvanella*-like and other sheath-calcified fossils (see below), and may be linked to CCM development in cyanobacteria, but in this case to planktic forms, possibly similar to present-day *Synechococcus* (Riding, 2006). Muddy carbonate platforms were the deposits in which distinctive molar tooth facies developed (James et al.,

1998; Sherman et al., 2000, p. 290). It can therefore be speculated that mid-late Proterozoic increase in micrites and molar tooth facies, together with *Girvanella* and thrombolites, all reflect decline in atmospheric CO_2 that stimulated CCM induction and calcification in cyanobacteria (Riding, 2006) (Figure 5).

Cyanobacterial sheath calcification: The first appearance of calcified cyanobacteria in the mid-Proterozoic – interpreted to reflect the first development of CCMs in photosynthetic organisms (Riding, 2006) – marked a radical change from stromatolitic to thrombolitic fabrics. Mesoproterozoic examples reported from the ~ 1200 Ma Society Cliffs Fm are currently the oldest known *Girvanella*-like calcified filaments, and are associated with micritic bush-like structures also interpreted as calcified cyanobacteria (Kah and Riding, 2007). The presence of filamentous fabrics had long been recognized in late Proterozoic and early Palaeozoic stromatolites. Microstructure with filament moulds was termed Canaliphorida and Filiformita by Komar (1976, 1989, see Bertrand-Sarfati et al., 1994, p. 182, Fig. 18). Aitken (1989, pp. 15–16) described “dendriform” and “lamelliform elements” as important components of Little Dal reefs in the Mackenzie Mountains. He regarded both as stromatolites with “unusual” or “unique” characteristics: thin-walled tubes and *Renalcis*-like objects in dendriform element, and a reticulate “ladder-rung” arrangement that “may be formed by a meshwork of tubes” in lamelliform element. He remarked that these fabrics “are not typically

stromatolitic” and that “sediment trapping may not have been the dominant process in their formation” (p. 15). Dendriiform and lamelliform elements look quite similar in two of his illustrations (Figs. 10 and 13). Subsequently, Turner et al. (1993, 2000a, Fig. 10b, 2000b) compared the tubules with *Girvanella* and noted that the lamelliform fabric consists of alternating dark layers of “calcimicrobial filaments” and lighter “more cement-rich” areas. Little Dal “hollow tubules with micritic walls” are figured by Batten et al. (2004, Fig. 9b). Knoll and Semikhatov (1998, p. 410, Figs. 3 and 4) described well-preserved “filmy or platy” microstructure in early Neoproterozoic *Baicalia lacera* stromatolites from the Chernaya Rechka Fm, Igarka, Siberia. They found it to be associated with “a distinctly filamentous microstructure” in which “laminae comprising densely interwoven to scattered, vertically, or subhorizontally oriented filaments are interspersed with layers of spongy or dense microspar.” They interpreted the 8–10 μm tubes as “sheaths of LPP-type (*Lyngbya*, *Phormidium*, *Plectonema*) cyanobacteria and preserved as drusy microspar encrustations” (Knoll and Semikhatov, 1998, p. 411). Similar *Baicalia lacera* fabrics in the $\sim 1\text{Ga}$ Burovaya Formation of west-central Siberia locally contain calcified tubes resembling *Siphonophycus* (Petrov and Semikhatov, 2001, p. 270). The lamelliform element shown by Turner et al. (2000a, Fig. 10b) resembles the distinctive “filmy” microstructure of similar age *Baicalia lacera* (Petrov and Semikhatov, 2001, Figs. 5b and 6a) which also has steeply dipping laminae and, as noted above, quite possibly filamentous microstructure too. In these examples, layers of filamentous fabric are generally interleaved with lighter, sparry, layers. If the sparry layers were lacking, the deposit would be indistinguishable from “skeletal stromatolite” (Riding, 1977) and “porostromate stromatolite” (Monty, 1981). In addition to the Little Dal and Chernaya Rechka examples, calcified filaments reminiscent of *Girvanella* are relatively widespread elsewhere

in the Neoproterozoic, e.g., in the ~ 750 – 700 Ma Draken Fm, ~ 725 – 675 Ma Svanbergfjellet Fm, and $\sim 700\text{ Ma}$ Upper Eleonore Bay Supergroup, Greenland (refs in Knoll and Semikhatov, 1998, p. 413). Throughout the Neoproterozoic, these thrombolites with calcified microbial fabrics (Kennard and James, 1986) are intimately associated with stromatolites but typically occur in deeper subtidal environments (Aitken, 1967).

Marine carbonate saturation

Inception of cyanobacterial calcification would have required overall seawater carbonate saturation to be relatively high. Grotzinger (1990) has argued that seawater saturation state progressively reduced during the Proterozoic and that this could account for concomitant decline in stromatolite abundance. Nonetheless, the widespread continued development of microbial carbonates into the Neoproterozoic, together with calcified sheaths themselves, indicates that saturation state was not low. This may have changed during widespread glaciations that occurred in the late Proterozoic ~ 700 – 570 Ma ago (Walter et al., 2000). Sheath-calcified cyanobacteria appear to have been scarce during “Snowball” glaciations. Lower temperature and $p\text{CO}_2$ levels would have decreased seawater saturation state, hindering microbial calcification generally. Shields (2002) attributed decline in Molar Tooth facies $\sim 750\text{ Ma}$ ago to reduction in carbonate saturation. Since cooling would also have favored diffusive entry of CO_2 into cells (Raven et al., 2002) it could have slowed CCM development, further reducing cyanobacterial calcification. As Earth emerged from these snowball glaciations, global warming and O_2 rise could have reactivated CCM development, and rising temperature, calcium, and $p\text{CO}_2$ levels would have increased seawater saturation state, stimulating calcification (Riding, 2006). Calcified cyanobacteria became relatively diverse

Calcified Cyanobacteria, Figure 6 Early Cambrian (Botomian) dendrolite-thrombolite reef, $\sim 70\text{ m}$ thick, near Tafraoute, Anti-Atlas Mountains, Morocco. Figures in foreground for scale.

in the earliest Cambrian (Nemakit-Daldynian) (Riding and Voronova, 1984) and were important components of Cambrian reefs (Riding, 2000; Rowland and Shapiro, 2002).

Calcmicrobial reefs and the Cambrian radiation

Calcified microfossils such as *Epiphyton*, *Renalcis*, and *Angusticellularia* are major components of Cambrian reefs (Figures 6 and 7) and similar forms reappeared in the late Devonian. The widespread development of microbial reefs in the early Cambrian may have directly contributed to marine invertebrate diversification. Reefs constructed by calcified microbes appeared in the latest Neoproterozoic, ~550 Ma ago (Grotzinger et al., 2000) and were common in Siberia, Altai Sayan, and Mongolia during the Nemakit-Daldynian (543–526 Ma ago) (Riding, 2002). In the Tommotian, 526–522 Ma ago, this reef-building association was augmented by archaeocyath sponges, with calcified microbes generally being volumetrically dominant (Rowland and Shapiro, 2002), and the reefs became large and cavernous. The exceptional biodiversity that characterizes reefs in general is largely due to the process of reef bioconstruction itself (Cocito, 2004). Rapid accretion of framework with synoptic relief and internal growth cavities creates substrates and spaces that differ in incident light, water movement, and sedimentation, as well as accessibility. This increased habitat size and partitioning generates heterogeneity that promotes biodiversity. For example, Cambrian trilobites show peak diversity in reefal environments (Westrop and Adrain, 2001), and comparison of level-bottom and reef communities in general shows that early Cambrian reefs were centers of diversity (Burzin et al., 2001, Fig. 10.2) with number of reef-building species comparable to that of late

Neogene fossil reefs (Kiessling, 2002, Fig. 20). The expansion of these globally distributed reef communities corresponded with rapid diversification of the shallow marine biota, especially during the Tommotian-early Botomian (~526–517 Ma ago) (Zhuravlev 2001, Fig. 8.1), suggesting a direct link between microbial carbonate development and metazoan evolution.

Phanerozoic record and secular controls

Cyanobacterial sheath calcification: Following their Mesoproterozoic inception, sheath-calcified cyanobacteria remained generally common in shallow-water marine carbonates during much of the Palaeozoic and until the late Jurassic (Arp et al., 2001) (Figure 8b). The abundance of sheath-calcified cyanobacteria during the early Palaeozoic (when CO₂ levels are thought to have been high, see Berner and Kothavala, 2001), suggests that CCMs continued to be induced even when pCO₂ substantially exceeded 10 PAL. This may reflect calcification in habitats subject to carbon limitation that induced CCMs, such as microbial mats and reefs (Riding, 2006). Nonetheless, enhancement of CCMs by overall decline in atmospheric CO₂ could be reflected by increased calcified-sheath abundance in the Mississippian, ~335 Ma ago (Riding, 2006) (Figure 5). However, it seems that this increase in calcified-sheath abundance promoted by falling CO₂ was itself terminated by subsequent steep decline in seawater saturation state ~325 Ma ago, before the end of the Mississippian (Figure 8a).

Broad similarities between calcified-sheath abundance and carbonate saturation are suggested by peaks in the late Cambrian (~500 Ma), late Silurian (~420 Ma), late Devonian (~370 Ma), late Triassic (~220 Ma), and late

Calcified Cyanobacteria, Figure 7 Early Cambrian calcimicrobial reef framework, showing clusters of mainly pendant filaments, early cement and geopetal cavity fill. Near Taroudannt, Anti-Atlas Mountains, Morocco. Width of view ~35 cm.

Calcified Cyanobacteria, Figure 8 Comparison of (a) Marine saturation ratio (Ω) for calcite, calculated from estimates of seawater and atmospheric composition, and (b) abundance of marine sheath-calcified cyanobacteria (Arp et al. 2001, Fig. 3d) (from Riding and Liang, 2005, Fig. 5). Obliquely ruled areas indicate five intervals approximately 500, 420, 370, 220, and 150 millions of years (Myr) ago where peaks of calculated saturation ratio broadly coincide with increased abundances of calcified cyanobacteria. This correspondence supports the view that cyanobacterial calcification has been increased at times of generally elevated seawater saturation for CaCO_3 minerals. The horizontally ruled area indicates the interval ~120–80 Myr ago in which high calculated saturation contrasts with low abundance of calcified cyanobacteria. This anomaly could reflect lowered Cretaceous carbonate saturation due to widespread deposition of pelagic carbonate by coccolithophore algae and globigerine foraminifers, since biological removal of CaCO_3 is not incorporated into the calculation of saturation values.

Jurassic (~150 Ma) (Figure 8), supporting the view that saturation state has significantly influenced the degree of cyanobacterial sheath calcification over geological time (Riding and Liang, 2005).

Reduced abundance of sheath-calcified cyanobacteria ~120–80 Ma ago contrasts with calculated saturation state which is elevated during this interval. This anomaly is thought to reflect reduction in actual (as opposed to calculated) saturation state due to burial of CaCO_3 precipitated as calcified skeletons by plankton such as coccolithophore algae and globigerine foraminifers (Riding and Liang, 2005). Such biological removal of calcium is not included in the input used to calculate the saturation values shown. This effect of planktic calcifiers on the seawater system may have continued into the Palaeogene. During the past 50 Ma, from the early Eocene onward calculated saturation has declined steeply in response to low values of Ca^{2+} ions and pCO_2 , and this is consistent with scarcity of marine calcified cyanobacteria. Consequently, although low pCO_2 values during the Cenozoic (see Berner and Kothavala, 2001) are expected to induce cyanobacterial CCMs, the absence of sheath calcification in marine cyanobacteria presumably reflects the overriding effect of low carbonate saturation.

Biogenic whittings: It can be inferred that, following the development of CCMs in the mid-Proterozoic, picoplanktic cyanobacterial activity could have been an important source of marine carbonate mud whenever inorganic carbon could be a limiting resource, as in plankton blooms (Rost et al., 2003), even when overall atmospheric CO_2 levels were high. If this is correct, then the principal factor determining biogenic whiting occurrence would have been carbonate saturation state. Calculations suggest that saturation was relatively elevated during much of the early-mid Palaeozoic and parts of the Mesozoic (Riding and Liang, 2005; and Figure 8a).

The origins of micrite are notoriously difficult to interpret even in present-day seas, and it is known that calcified green algae can also be significant producers (Stockman and Ginsburg, 1967). How can the possible contribution of biogenic whittings therefore be assessed in the geological past? One line of reasoning is to assume that sheath-calcified cyanobacteria reflect generally similar conditions to those that favor picoplanktic whiting precipitation. The geological record of sheath-calcified fossils such as *Girvanella* is relatively well-documented, and they show marked fluctuations in abundance (Arp et al., 2001, Fig. 3d) (Figure 8b). It could therefore be predicted that picoplanktic mud should show a similar pattern of

abundance, with peaks for example in the late Cambrian, Devonian-Mississippian, and late Jurassic. It should be possible to test whether carbonate mud was relatively abundant at these times. It is also possible that biogenic whittings – and sheath calcification – should have been further intensified whenever $p\text{CO}_2$ levels fell to levels near or below ~ 10 PAL, as for example ~ 350 Ma ago (Figure 5).

Cenozoic decline in seawater carbonate saturation, suggested by calculations based on modeled values (Riding and Liang, 2005, Figs. 5a and 8a), would be expected to have reduced biogenic whiting precipitation. Certainly, sheath calcification is scarce to absent during most of the past 100 Ma (Arp et al., 2001, Fig. 3d) (Figure 8b). In this context, it is not surprising that there is uncertainty whether present-day marine whittings on the Bahaman Banks are biogenic or mainly reflect sediment resuspension (Broecker et al., 2000). From a geobiological perspective, however, even if present-day marine conditions do not greatly favor phytoplankton-stimulated precipitation of whittings, these may have been very important at times in the geologic past environment when carbonate saturation state was sufficiently high. If this is correct, biogenic whittings could account for a substantial part of the carbonate mud that accumulated on shallow shelves between the late Mesoproterozoic and Mesozoic.

Summary

Calcified cyanobacteria are easily overlooked fossils, yet their long history coupled with their sensitivity to environmental controls on their calcification, make them potentially significant indices of changes in seawater chemistry and atmospheric CO_2 level throughout the Proterozoic and Phanerozoic. Locally they are also sedimentologically important reef components, and they have played a major role in the formation of calcimicrobial thrombolites that are especially widespread in the Neoproterozoic and early Palaeozoic. At the present day their vanishing scarcity in marine environments is thought to reflect relatively low seawater carbonate saturation that has persisted throughout the Cenozoic. However, their local abundance in oncoids and tufas of freshwater calcareous streams and lakes, and their involvement in lacustrine whittings, are reminders of the ability of cyanobacteria to promote intense CaCO_3 deposition when conditions that include ambient saturation state, are favorable.

CALCITE PRECIPITATION, MICROBIALY INDUCED

Tanja Bosak

Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Microbially induced calcite precipitation describes the formation of calcium carbonate minerals from a solution due to the presence of microbial cells, biosynthetic products, or metabolic activity.

Calcium carbonate precipitation

The most basic requirement for the precipitation of calcium carbonate (CaCO_3) minerals, calcite, and aragonite is that the product of the concentrations of calcium $[\text{Ca}^{2+}]$ and carbonate ions $[\text{CO}_3^{2-}]$ exceeds the solubility product of calcite (Equation 1) and aragonite, respectively.

$$[\text{Ca}^{2+}][\text{CO}_3^{2-}] > 10^{-8.35} \quad (1)$$

The solubility of carbonate minerals depends on the temperature and pressure, decreasing with increasing temperatures and increasing with the increasing pressure. When a solution is in equilibrium with carbon dioxide, $[\text{CO}_3^{2-}]$ is determined by pH. In solutions that are undersaturated or not highly saturated, such as modern seawater, the biological activity can strongly control the precipitation of CaCO_3 . Biological processes exert considerably less control on the precipitation of CaCO_3 in environments characterized by high temperature, high pH, and high evaporation and degassing rates such as soda lakes, hot springs, caves, and freshwater tufas.

Microbial processes that promote the precipitation of CaCO_3

Culture-dependent and culture-independent studies have shown that microbes (Bacteria and Archaea) can induce extracellular precipitation of calcium carbonate minerals by:

- Increasing the local pH and the concentration of carbonate ion
- Promoting the nucleation of calcium carbonate minerals and removing the kinetic inhibitors of CaCO_3 precipitation.

Increase in local pH and the concentration of carbonate ion

Because the concentration of carbonate ion increases with the increasing pH, the precipitation of calcium carbonate minerals will also increase with the increasing pH. Many microbial metabolic processes can increase the pH and/or the concentration of carbonate ions: sulfate reduction in marine sediments (Dupraz and Visscher, 2005; Van Lith et al., 2003; Visscher et al., 2000), oxygenic

photosynthesis in freshwater streams and lakes (Merz-Preiß and Riding, 1999; Thompson et al., 1997), anaerobic methane oxidation coupled with sulfate reduction in marine sediments (Reitner et al., 2005), denitrification, degradation of amino-acids and small organic acids (Chekroun et al., 2004), and degradation of calcium oxalate in soils (Braissant et al., 2002). Whether microbes are able to significantly increase local pH and $[\text{CO}_3^{2-}]$ will largely depend on the buffering of the medium by dissolved inorganic carbon. Microbial activity in poorly buffered solutions such as lakes and streams is more likely to influence the saturation state of CaCO_3 (Merz-Preiß and Riding, 1999) than in well-buffered solutions such as soda lakes, hot springs, and solutions analogous to the early soda oceans (Arp et al., 1999a, b; Bosak and Newman, 2005).

Precipitation of calcium carbonate minerals also can be inhibited by the adsorption of various metabolites such as phosphate, sulfate, and organic moieties onto the faces of the growing crystals (Bosak and Newman, 2005; Liu and DeYoreo, 2004; Plant and House, 2002; Teng et al., 1998). Microbial growth and metabolic processes that lower the concentration of these ions in the solution can promote the precipitation of minerals even when they do not significantly influence pH and $[\text{CO}_3^{2-}]$ (Bosak and Newman, 2005; Kawaguchi and Decho, 2002).

Nucleation of calcium carbonate minerals on organic surfaces

Minerals can nucleate either homogeneously on the surface of preexisting carbonate grains, or heterogeneously on organic or other surfaces. When the external calcium carbonate sediment is sparse or absent, nucleation is the most energetically expensive step in the precipitation of calcium carbonate minerals. Organic matter can lower the free energy barrier required to form the initial nuclei, thus promoting mineral formation. Nucleation of CaCO_3 on organic surfaces (i.e., heterogeneous nucleation) occurs when negatively charged surface groups such as carboxylate, phosphate, and sulfate complex bind calcium. Although this process can initially inhibit the precipitation of minerals, once the local concentrations of calcium and carbonate has exceeded the binding capacity of the organic matrix, or when the matrix is partially degraded, mineral nucleation occurs preferentially on the organic template (Arp et al., 2003; Braissant et al., 2003; Decho et al., 2005). Heterogeneous nucleation can increase the number of crystal nuclei even when the bulk medium is supersaturated with calcium carbonate by more than an order of magnitude (Arp et al., 1999b; Bosak and Newman, 2003).

Heterogeneous nucleation of CaCO_3 can take place on the cell surfaces and envelopes, or within the exopolymeric matrix surrounding microbial cells. Examples of the former are the calcification of the sheaths surrounding cyanobacterial cells (Merz-Preiß and Zankl, 1993) and the whitening events caused by the precipitation of calcite on the outer S-layer of some planktonic

cyanobacteria (Thompson et al., 1997). These processes are most commonly observed in freshwater environments and require actively photosynthesizing cyanobacteria (Thompson et al., 1997). Cyanobacteria encrusted by CaCO_3 are considerably less abundant in modern marine calcium carbonates (Arp et al., 2001). Similarly, the relationship between marine whittings and cyanobacterial presence and activity has not been demonstrated conclusively (Thompson, 2000). Instead, in marine photic zones, carbonate minerals precipitate mainly within the extracellular exopolymeric matrix in areas of heterotrophic degradation (Chafetz and Buczynski, 1992; Dupraz and Visscher, 2005; Gautret et al., 2006; Van Lith et al., 2003; Visscher et al., 2000). In addition to the nucleation on exopolymeric substances or cell surfaces, CaCO_3 also preferentially nucleates around submicron vesicles that are secreted by sulfate-reducing bacteria (Aloisi et al., 2006). The nucleation of CaCO_3 on these vesicles may be a common mechanism in the environment, because outer-membrane vesicles are secreted by many Gram-negative bacteria (Beveridge, 1999; Kuehn and Kesty, 2005).

Recognition of microbially induced CaCO_3 precipitates in the rock record

Even when microbes do not induce measurable changes in the chemical composition of the bulk solution, they can alter the pH and carbonate chemistry, remove kinetic inhibitors, and promote mineral nucleation and precipitation at a microscale (Figure 1). When minerals precipitate, surrounded by microbial cells and microbial aggregates (biofilms) (Figure 1), they can preserve remnants of organic matter, such as acidic amino acids and microbial casts, long after the original cells have been degraded (Bosak et al., 2004a; Sprachta et al., 2001). Furthermore, CaCO_3 precipitated in the presence of organic compounds often has distinct shapes (Bosak and Newman, 2005; Braissant et al., 2003; Chafetz and Buczynski, 1992; Teng et al., 1998), although similar shapes can also be produced abiotically.

Biological influence on the morphology of carbonate crystals and structures is most prominent in skeleton-building organisms. Macroscopic and microscopic eukaryotic organisms such as calcareous algae, protists, corals, and mollusks precipitate hard body parts. Many of these organisms precipitate CaCO_3 by genetically encoded mechanisms that result in shells, skeletons, and carbonate grains with species-specific shapes. In contrast to these products of biologically controlled calcification, the shapes of microbially induced carbonate minerals can be distinguished from abiotically precipitated grains rarely (Golubic et al., 2000). Consequently, the potential identification of biosignatures of microbially induced carbonates in modern and past sedimentary carbonates can be controversial (Grotzinger and Knoll, 1999).

Recognition of microbially induced carbonates is also impeded by the difficulty in distinguishing between CaCO_3 structures that grew *in the presence* of microbes

Calcite Precipitation, Microbially Induced, Figure 1 Aragonite precipitated on cyanobacterial biofilms (BF) floating in solution. (a) Photograph of a thin cyanobacterial biofilm with visible aragonite precipitates that preserve the biofilm. *White arrows* mark the densest mineral aggregates. (b) Transmitted-light micrograph of cyanobacterial filaments trapping small mineral grains (*white arrows*) in lightly mineralized areas. (c) Epifluorescence micrograph (deconvolved) of the same field of view as in (b). Cyanobacterial filaments fluoresce *red* and the nuclei of other microbes are stained *green*. Note that the mineral grains are surrounded by microbial aggregates that are not cyanobacteria (and are, presumably, heterotrophic). Scale bar: 5 mm in a, 5 μ m in b and c.

or organic matter from structures that grew *because* of microbial activity. Some examples of carbonate grains and structures with often ambiguous origin include peloids, ooids (Figure 2), whittings, fossil stromatolites, and nanobacteria. Recent developments in analytical techniques such as X-ray microscopy have enabled the detection of small quantities of fossil organic matrices in fossil carbonates at the microscale, thereby establishing that some fossil carbonates grew in the presence of microbes (Benzerara et al., 2006; Lepot et al., 2008). Despite the inclusion of organic matter, the role of biology in forming these structures remains unknown. As an alternative approach, experimental and quantitative models of the morphogenesis of sedimentary structures at the macroscale and microscale have been developed in an attempt to understand which fossil structures and shapes require biological processes (Batchelor et al., 2004; Bosak et al., 2004b; Dupraz et al., 2006; Grotzinger and Rothman, 1996; Reid et al., 2000; Suess and Futterer, 1972).

Summary

The potential of microbes to induce precipitation of calcium carbonate has sparked scientific interest for almost a century. The calcium carbonate (CaCO_3) minerals, calcite and aragonite, often precipitate in association with microbial cells and biofilms in marine and terrestrial sedimentary environments such as reefs, lakes, streams, beaches, soils, hot springs, and caves. Being ubiquitous and relatively insoluble, these minerals have helped preserve bacterial and archaeal cells and biofilms throughout geologic time (Figure 1). Microbes promote the precipitation of calcium carbonate metabolically, by increasing the pH and the alkalinity of their surroundings, or by the secretion of substances that facilitate the mineral nucleation. The recognition of microbially influenced calcium carbonate precipitates in the rock record is often challenging because abiotic carbonate precipitation can produce

Calcite Precipitation, Microbially Induced, Figure 2 An example of carbonate grains of controversial origin. Scanning electron micrograph of a thick polished section of late Jurassic ooids (rounded grains with layered interior structure) precipitated on the Adriatic Platform, Croatia, in low-energy, shallow water settings (Husinec and Reid, 2006). Ooids from low-energy environments were commonly interpreted as largely inorganic precipitates that adsorb organic molecules (Davies et al., 1978). More recently, cyanobacteria and other microbes have been shown to contribute to the formation of low-energy ooids and meniscus cements (M) (Brehm et al., 2006; Hillgartner et al., 2001; Plee et al., 2008). Although microbes may have contributed to the formation of ooids shown here, these grains do not preserve any textural evidence of the former presence of microorganisms. Scale bar: 100 μ m.

crystals with similar shapes and chemical signatures. Current research in the field of microbial carbonates tackles this challenge by conducting culture-dependent and culture-independent studies of microbial mineral precipitation, employing analytical techniques that can detect

small quantities of organic matter in fossil carbonates, and by developing theoretical models that explain the shape of macroscopic carbonate sedimentary structures. Microbially induced precipitation of carbonate minerals is likely to garner even more interest in the future with a primary focus on carbon sequestration, the production of biomimetic materials, and the conservation of ornamental stone.

Definition

Calcium (Ca) has the atomic number 20 and is an alkaline earth metal with an atomic mass of 40.978 amu. The

important role of Ca in biogeochemical processes is based on its chemical versatility, which is related to its highly adaptable coordination geometry, its divalent charge, modest binding energies, fast reaction kinetics, and its inertness in redox reactions (Williams, 1974). Calcium is a soft grey alkaline earth metal, and is the fifth most abundant element in the Earth's crust and the seventh most abundant element in the ocean. It is essential for living organisms, particularly in cell physiology, shell formation, and calcification and hence, is usually the most common metal in many animals.

Calcium isotopes and their application in Biogeochemistry

There are seven Ca isotopes present in nature of which three isotopes (^{42}Ca (0.646%), ^{43}Ca (0.135%) through ^{44}Ca (2.086%)) are stable, one isotope (^{40}Ca (69.941%)) is radiogenic, one isotope (^{41}Ca) is cosmogenic, and two more isotopes (^{46}Ca (0.004%) and ^{48}Ca (0.187%)) are radioactive having extremely long half-lives (^{46}Ca : $2.8 \cdot 10^{15}$ years; ^{48}Ca : $> 4 \cdot 10^{19}$ years). The cosmogenic isotope ^{41}Ca is radioactive (half live of 103,000 years) and is produced by neutron activation of ^{40}Ca in the upper soil column. ^{41}Ca has received much attention in stellar studies because it decays to ^{41}K , a critical indicator of solar system anomalies. ^{40}Ca is the radiogenic daughter product of ^{40}K decay, along with ^{40}Ar . While K–Ar dating has been used extensively in the geological sciences, the prevalence of ^{40}Ca in nature has impeded its use in dating. Techniques using mass spectrometry and a double spike isotope dilution have been used for K–Ca age dating (Nägler and Villa, 2000).

Natural Ca isotope fractionation has, among other isotope systems such as oxygen (d^{18}O) and carbon (d^{13}C) fractionation, been applied for the study of calcification processes and the so-called vital effect (c.f. Gussone et al., 2003; Lemarchand et al., 2005). Latter effect describes the deviation of the expected inorganic isotope fractionation value or element partitioning coefficient (e.g., Sr/Ca, Mg/Ca, etc.) from the measured one in calcifying organisms such as coccolithophores, foraminifer, corals, and other calcifying organisms.

The more or less species-dependent Ca isotope fractionation of marine calcifying organisms as a function of the adjacent seawater temperature can be applied for the reconstruction of the dynamic of Ca concentrations throughout the Earth's history (c.f. Griffith et al., 2008; Farkas et al., 2007; Heuser et al., 2005; Fantle and DePaolo, 2005; De LaRocha and DePaolo, 2000) and for the reconstruction of past sea surface temperatures (c.f. Nägler et al., 2000; Hippler et al., 2006).

The dynamic of calcium in the ocean

Calcium is the second most abundant divalent cation (~ 10 mmol/l), besides magnesium (Mg, ~ 52 mmol/l). Calcium is considered to be a conservative element in the ocean water column, with a residence time of about

one million year. A number of scientific studies show that continental and oceanic weathering, mid-ocean ridge hydrothermal activity, and carbonate sedimentation are the major factors controlling the marine Ca cycle (Hart, 1973; Thompson, 1983; Zhu & Macdougall, 1998; Berner, 2004). Besides continental weathering and riverine influx, comprising about 70% of the Ca flux to the ocean, submarine magmatism and associated hydrothermal activity at the mid-ocean ridges as well as seafloor weathering are also recognized to be major sources for the marine Ca budget (Berner & Berner, 1996). A number of studies indicated that Ca is released from the oceanic crust during water–rock reactions ranging from high-temperature hydrothermal interactions to seafloor weathering at low temperatures below about 150°C (Berner, 2004; Amini et al., 2008). Ca-bearing mineral phases such as aragonite, calcite, anhydrite, and subordinately hydrous Ca-silicates (e.g., prehnite, zeolites) are formed during different stages of ocean crust alteration.

Marine calcification

The dynamic of Ca in the ocean is of particular interest because of the formation of biogenic and nonbiogenic calcium carbonate (CaCO_3), known as the process of calcification, and its interference and close linkage with the global carbon cycle (c.f. De LaRocha & DePaolo, 2000; Heuser et al., 2005). In particular, the formation of calcareous skeletons by marine planktonic organisms and their subsequent sinking to depth generate a continuous rain of CaCO_3 to the deep ocean and the underlying sediments. This is important in regulating marine carbon cycling and ocean–atmosphere CO_2 exchange. The present rise in atmospheric CO_2 levels causes a significant decrease (acidification) in surface ocean pH and a major change of carbonate chemistry. Laboratory experiments have shown that such changes slow down calcification in corals and coralline macroalgae. Over geological time scales, the Ca balance in the ocean is believed to be directly related to pCO_2 variations in the atmosphere, and it thus may interfere with climate changes on geological time scales (e.g., Demicco et al., 2003; Fantle and DePaolo, 2005).

Summary

Future progress in instrumental analytic will allow high-resolution measurement of Ca elemental and isotope partitioning in inorganic and biological systems, allowing to trace elemental pathways from a bulk solution to the site of calcification.

CAP CARBONATES

Joachim Reitner
University of Göttingen, Göttingen, Germany

Definition

Cap carbonates are unusual deposits of dolostones and limestones, often enriched in barite, that sharply overlie Neoproterozoic glacial deposits. They are from 2 to 50 m thick and occur on shallow platforms, shelves, and

Cap Carbonates, Figure 1 Marinoan ca. 635 My cap carbonate from Namibia (Fransfontein, Otavi Mountains). Characteristic features of this cap carbonate (mainly dolomite) are syndementarily formed Zebra Limestone-type fabrics. The horizontal fractures were originally cemented with large aragonitic crystals. The remaining pore spaces are filled up with cherts.

Cap Carbonates, Figure 2 Sturtian ca. 750 My old cap carbonate from Namibia (Rasthof cap carbonate, Baesvalkte). These black laminated carbonates are lithified microbial mats. Very common are “roll up structures” which are known from many microbial mat systems, even from modern ones.

slopes worldwide, even in regions otherwise lacking in carbonate strata.

Glaciation events during the late Neoproterozoic (Cryogenian–Ediacaran) are widespread on Earth, reflecting up to four global ice ages (“Snowball Earth Hypothesis”) between 730 and 580 Ma. Numerous publications dealing with these events exist (for example, see Chapter by Hoffman P.F., Snowball Earth, this volume; Shields, 2005; Jiang et al., 2003). Some of them exhibit characteristic, microcrystalline cap dolostones, and also limestones, which is unique and reflects a climate paradox. Particularly the Marinoan glaciation ca. 635 Ma ago is peculiar, because it provides evidence for low altitude glaciation at equatorial latitudes. Three models have been proposed to explain an increase in alkalinity inducing these global carbonate formation events:

(1) Overturn of an anoxic deep ocean; (2) enormous rates of chemical weathering in the hinterland after glaciation (Snowball Earth Hypothesis); (3) destabilization of methane clathrates and increase of alkalinity caused by anaerobic oxidation of methane (AOM). However, none of the hypotheses sufficiently explains the consistent sequence of precipitation events observed within cap carbonate successions. The formation of massive dolostones is very problematic and hardly understood. Massive microbial sulfate reduction may explain this event. Barite precipitation is also very common. The source of sulfate is most probably the weathered hinterland. Caused by seawater oversaturated with aragonite, diagenetically very early large aragonite crystals were formed. It is suggested that cap carbonates are primarily formed by a microbially mediated precipitation. Possibly, the highly oxygenated shallow marine environments of the postglacial Neoproterozoic oceans provided excellent conditions for the evolutionary development of new microbial communities, phototrophic organisms, and of course, the rapid development of Metazoa (Figures 1 and 2).

CARBON (ORGANIC, CYCLING)

Amber K. Hardison, Elizabeth A. Canuel
Virginia Institute of Marine Science, Gloucester Point,
VA, USA

Definition

Organic carbon (OC) refers to any carbon that occurs in compounds of ultimately biological origin that can be oxidized.

Introduction

Carbon is made up of organic and inorganic fractions, and the biochemical and geochemical cycling of these forms through the Earth processes is referred to as the global carbon cycle. The global carbon cycle is closely linked to other global cycles such as oxygen, nitrogen, and sulfur because of the important role these elements play in biological processes. Organic carbon (OC) is present in both living and nonliving systems and ultimately fuels all of the Earth's biogeochemical processes (Summons, 1993); therefore, understanding the formation, cycling, and preservation of OC is essential to understanding the cycling of

all bioelements between living and nonliving reservoirs, the formation of economically important petroleum and coal deposits, and predicting how human activity may change the natural balance of these systems.

Much of the OC created during photosynthesis or by chemosynthetic autotrophs is decomposed by heterotrophic organisms. Heterotrophic processes occur in the water column of marine and aquatic environments, as well as in sediments, soils, and rocks. Much of the decomposition of organic matter (OM) occurs under low temperature (<50°C) and pressure during diagenesis. Diagenesis occurs primarily through biological processes (microbes and larger organisms that live in surface sediments) and over depths ranging from microns to hundreds of meters. The OC preserved following diagenesis is subject to further alteration by the processes of catagenesis and metagenesis, which occur at higher temperatures and pressures and lead to the formation of petroleum and natural gas.

Reservoirs

The cycling of OC involves fluxes to and from the major OC reservoirs (Figure 1). Sedimentary rocks are the largest OC reserve, making up approximately 99.5% of the

Carbon (Organic, Cycling), Figure 1 The global organic carbon (OC) cycle, adapted from Hedges (1992). The OC cycle involves fluxes to and from the major surficial and deep reservoirs. Reservoirs are denoted by capital letters, with values in blue. Fluxes due to physical processes (italicized) and primary production (not italicized) are denoted with *arrows*. Flux terms are presented in lower case font, with values given in red. Information presented in this figure is based on published values from Schlesinger (1991), Longhurst (1995), Hedges et al. (1997), Kvenvolden (2002), Richey (2004), IPCC (2007).

total global OC. Despite the relative size of this reservoir, OC only represents one-fifth of the total sedimentary carbon, since inorganic carbon is the dominant fraction (Hedges, 1992). Sedimentary OC occurs primarily as kerogen, coal beds, and petroleum reservoirs, which ultimately come from biogenic processes or sources. Kerogen is an amorphous, highly insoluble particulate OM that is thought to form by two pathways – selective preservation and geopolymerization, both of which occur under low temperature and pressure conditions (Killops and Killops, 2005). Selective preservation involves the formation of kerogen from biomacromolecules that are resistant to microbial degradation. Geopolymerization occurs through a random series of condensation and polymerization reactions involving humic substances. Petroleum is defined as naturally occurring fluid (liquid and gases) that evolves from kerogen. Petroleum is formed primarily from the remains of microbes (algae and bacteria), although some types of petroleum are formed from higher plants. In contrast, coal is a solid and is formed from the remains of higher plants. The most common type of coals, humic coals, is formed through the processes of peatification and coalification, which involve both biological and geochemical processes (Killops and Killops, 2005). The OC in ancient sedimentary rocks provides these economically important fossil fuels as well as a molecular record of life, which has allowed the construction of evolutionary trees and an understanding of the geologic timing of past events and the response of natural systems to tectonic, environmental, and biological change (Brocks and Pearson, 2005). Historically, sedimentary OC affects biologically mediated cycles on geologic time scales, although humans have recently accelerated this cycle through fossil fuel combustion (7.5×10^{15} g C year⁻¹; IPCC, 2007).

The active (surficial) pools of OC include soil humus, land and marine plant tissue, seawater dissolved OC (DOC, <0.5 μ m diameter), and surface marine sediments and gas hydrates (Kvenvolden, 2002; Hedges, 1992). Dead and living particulate OC (>0.5 μ m) are also present in freshwater and seawater pools; however, the DOC pool dominates. With the exception of plant tissue and gas hydrates, most of the active pools of OC are poorly characterized. Terrestrial plant tissue can be further classified as woody biomass (~75%), nonwoody biomass (~15%), and litter (~10%) (Olson et al., 1985). Gas hydrates contain mostly methane and some ethane molecules, and may serve as a large reservoir for OC, although global estimates of the size of this sink are still uncertain (see Kvenvolden, 2002). Soil OM is made up of plant remains (detritus), soil microbes, and humic substances.

Production and fluxes

The major fluxes between organic pools are driven by marine and terrestrial primary production. Photosynthesis, the harvesting of light energy to convert inorganic carbon

to reduced (organic) forms in the tissue of plants, is the primary mode of primary production. However, chemosynthesis by microbial organisms, which uses chemical energy rather than sunlight, is also important. Photosynthesis is carried out by prokaryotes such as cyanobacteria as well as eukaryotic algae and higher plants. The fixation of carbon by plants over the Earth's history accounts for the oxygen in our present atmosphere, thus the cycles of carbon and oxygen are closely linked over geologic time (Hedges, 2002; Hedges and Keil, 1995). In fact, to maintain current atmospheric oxygen levels, rapid cycling of carbon in the surficial pools is required. These pools exchange on relatively short timescales (10^2 – 10^4 years). In contrast, the OC that remains in the sedimentary system cycles slowly (~ 10^8 year; Schlesinger, 1991). Sedimentary reservoirs only become exchangeable through geologic uplift, followed by oxidative weathering of OC by exposure to the atmosphere.

Net global primary production (NPP) on land (45 – 65×10^{15} g C year⁻¹) is dominated by more labile nonwoody plant tissues such as leaves, grasses, and herbaceous annuals (Schlesinger, 1991). The highest gross terrestrial production (82×10^{15} g C year⁻¹) and storage as biomass (56%) occur in the tropics, while polar regions contribute the least (8×10^{15} g C year⁻¹, 0.5%; Taube, 1992). Within these regions, forests are the most productive continental biomes and deserts and tundra are the least (Taube, 1992), reflecting global patterns of temperature and precipitation. Marine primary productivity ($\sim 50 \times 10^{15}$ g C year⁻¹) is dominated by open water (pelagic) phytoplankton productivity because open water constitutes approximately 75% of the total ocean area (Ducklow and McCallister, 2005; Longhurst, 1995). However, when normalized to area, coastal and upwelling areas together account for nearly two thirds of the total oceanic productivity because a greater supply of nutrients is available to support phytoplankton in these areas (Longhurst, 1995). Other primary producers along the coasts (i.e., seagrass, marsh plants, macroalgae, mangroves) are locally important sources of OC.

Delivery of OC (as both dissolved and particulate fractions) from the land to coastal marine environments by rivers accounts for 0.4×10^{15} g C year⁻¹ (Meybeck, 1982; Ittekkot, 1988). However, there remains considerable uncertainty in our ability to adequately quantify carbon exchange from land to the coastal ocean and in our understanding of the processes influencing the fate of terrigenous carbon in coastal sediments (Berner, 1982; Sarmiento and Sundquist, 1992; Hedges and Keil, 1995; Schlünz and Schneider, 2000). Generally, the total annual riverine OC load to the ocean is proportional to the total annual river flow, which is dominated by a small set of rivers that transport the bulk of the fresh water from land to sea (Schlesinger, 1991). However, seasonal and annual/interannual variations in hydrology as well as large events such as storms and hurricanes influence the input, dispersion, and cycling of sediment OM in coastal environments, thus making it difficult to trace terrigenous OM.

In addition, recent molecular and isotopic evidence suggests that OC in seawater and marine sediments is marine, rather than terrestrial, in nature, which suggests that further remineralization of terrestrial material must occur in rivers prior to delivery to the coastal ocean (Schl nz and Schneider, 2000; Richey, 2004; Mayorga et al., 2005) or in the marine environment (Hedges et al., 1997). This is an area requiring further research. Eolian (air) flux from the land to the sea approximates 0.1×10^{15} g C year⁻¹, although this estimate remains uncertain due to methodological difficulties (Romankevich, 1984; Zafiriou et al., 1985).

Decomposition and preservation

Only ~0.1% of global NPP is ultimately preserved within sediments; however, it is this OC that will eventually become part of the sedimentary record and may be transformed into fossil fuels. The remaining 99.9% of global NPP is remineralized to inorganic carbon, nutrients, and water. Remineralization represents a sink for oxygen, linking the global cycles of OC and oxygen. Microfauna, bacteria and fungi (on land) are responsible for the breakdown of OM. Bacterial and fungal decomposition of OM involves a series of steps; macromolecules must first be broken down using extracellular enzymes into dissolved polymers, which are then broken down into low molecular weight monomers (Tissot and Welte, 1984).

The rates and extent of decomposition are influenced by environmental, biological, and physical factors. First, there must be a sufficient supply of labile OM to be degraded. The depth-integrated rate of OM remineralization in marine sediments correlates closely with carbon flux to the sediment surface (Henrichs, 1993). Interestingly, the fraction of OC that is *not* remineralized is also highly correlated with the carbon flux to the sediment surface. Thus, the efficiency of OM decomposition appears to be lower in systems that receive the highest input of OC compared to systems with lower accumulation rates (Henrichs and Reeburgh, 1983). Second, like most metabolic processes, decomposition rates are proportional to temperature, resulting in global patterns of decomposition rates (e.g., higher degradation rates in the tropics than in tundra systems) (Schlesinger, 1991). Oxygen is also a controlling factor for decomposition. Recent evidence suggests that oxygen exposure time, rather than oxygen concentration, may be an important determinant of the extent to which OM is decomposed (Hartnett et al., 1998). OM decomposition occurs under both oxic and anoxic conditions; however, the rates and bacterial communities involved in the processes differ. Oxygen is used preferentially as the terminal electron acceptor during decomposition and results in the most efficient mineralization (i.e., the highest energy yield). Once oxygen is depleted, bacteria utilize other electron acceptors such as sulfate and nitrate. Aerobic decomposition is facilitated

by microbes as well as higher organisms with a range in enzyme capabilities. Anaerobic decomposition is carried out exclusively by microorganisms, and complete remineralization is typically dependent on a consortium of cooperating organisms. Further, anaerobic decomposition processes differ in terrestrial and marine environments because sulfate is abundantly present in marine systems but limited in terrestrial systems. As a result, sulfate reduction is the dominant anaerobic pathway for oxidizing OM in marine systems, while fermentation and methanogenesis dominate in freshwater systems (Henrichs, 1993). The chemical and structural makeup of OM also plays a role in its susceptibility to decomposition (e.g., number of double bonds and functional group composition). For example, nitrogen-rich compounds such as proteins and polynucleotides are usually decomposed preferentially to carbon-rich structural compounds (Wakeham and Canuel, 2006). Additionally, the architecture of the OM may be an important control on its decomposition. Architecture refers to both physical structure (e.g., conformation) as well as OM associations with organic and inorganic matrices (see below).

Decomposition and preservation of OC are closely linked processes, since only OC that is not decomposed is available for preservation, but there are additional factors that may enhance preservation (Burdige, 2007; Wakeham and Canuel, 2006). For instance, the amount of OC that reaches the sediment surface and has the potential to be buried depends in part on productivity in the overlying photic zone and water depth. Sufficiently high productivity is essential for OC to reach the sediment with the potential for preservation (Killops and Killops, 2005). In addition, physical or chemical protection of OM plays a key role in controlling preservation. Protection by binding to inorganic ions, clays, and organic residues decreases the surface area of OM that is exposed to bacteria for degradation. This protection or encapsulation of OM explains why compounds that appear to be labile, or readily available for decomposition, have been found in sedimentary OC deposits. Lastly, the amount of time that OM is exposed to oxic conditions determines the extent to which oxygen-sensitive compounds, compounds that specifically require oxygen for degradation, are preserved (Burdige, 2007).

Preservation of OC occurs predominantly in anoxic marine sediments. More than 80% of preserved OC is located in deltaic-shelf environments associated with fine grain sediments (Bernier, 1982) that support the physical or chemical protection model, since these sediments provide the most potential surface area with which OM can bind. This has likely been true for millions of years, as current petroleum deposits are found in areas that were formerly coastal, fine grained sediments. Major depositional environments include lacustrine environments (open, closed lakes), peat swamps and coal, and continental margins, enclosed or silled basins, and the Black Sea (Killops and Killops, 2005).

Conclusion

The global OC cycle involves exchange of OC between surface and subsurface (buried) reservoirs on time scales of less than one year to millions of years. These fluxes are driven by the production and cycling of OC through biological, physical, and geological processes. The global OC cycle is intimately linked with other global cycles and is sensitive to human-induced perturbations. Humans may have reduced total NPP by up to 40% due to wildfires and pollution, which may be the largest sink for primary production to support a single species in the history of life on the Earth (Vitousek et al., 1986). Fossil fuel combustion and destruction of forests (especially tropical) have decreased the global pool of OC and increased atmospheric carbon dioxide, which has been linked to global climate change. Global atmospheric concentrations of CO₂, methane (CH₄), and nitrous oxide (N₂O) have increased markedly as a result of human activities since preindustrial times (i.e., 1,750). In 2005, concentrations of atmospheric CO₂ (379 ppm) and CH₄ (1,774 ppb) exceeded the natural range over the last 650,000 years (IPCC, 2007). Understanding the changes in the size and composition of the OC reservoir through space and time will help us to better predict the changes in its global cycle as well as the associated cycles of other biologically important elements.

Synonyms

Carbon biodegradation; Carbon remineralization

Definition

Organic carbon (OC). In geochemistry, carbon that occurs in materials of ultimately biological origin and that can be oxidized. Organic matter (OM) is the material that contains organic carbon (OC).

Degradation. Transformations of OM within the range of temperatures, pressures and environmental conditions found in or near the Earth surface environments. If biological activity is confirmed to cause the transformations, it is termed biodegradation.

Remineralization. Degradation of OM that results in net conversion of OC to inorganic (oxidized) carbon species such as CO_2 or HCO_3^- .

Introduction

The Earth exists in a near balance between photosynthesis and respiration. Photosynthesis, by which inorganic carbon is chemically reduced to biologically-available OC using light energy, generates an estimated 107 Pg C of net new production each year (1 Pg = 10^{15} g), nearly evenly distributed among terrestrial (57 Pg C year⁻¹) and marine (50 Pg C year⁻¹) environments (Field et al., 2007; Sabine et al., 2004). Of this biomass, over 90 Pg C is remineralized each year to inorganic carbon

through aerobic respiration on land and in the oceans, leaving 17 Pg year⁻¹ to be redistributed among different pools of nonliving OM (Field et al., 2007; Sabine et al., 2004). These pools include soils, aquatic and marine sediments, and nonliving OM in the world's oceans. Degradation of organic carbon in these pools balances the crustal carbon cycle, such that total global respiration plus net OC remineralization are believed to match global rates of photosynthesis (Bernier, 2003). Maintaining or slowly shifting this balance has been a critical component of the coupled atmosphere–ocean climate system throughout the Earth's history, and has served to maintain an equable amount of atmospheric oxygen (O_2) for the past 600 million years (Bernier, 1989, 2003).

Degradation of OC in soils

Soils contain complex mixtures of weathered rocks, new minerals formed within soils, and OM. The world's soils contain an estimated 3,200 Pg C (Sabine et al., 2004 and references therein). Much of this OM derives from terrestrial vegetation. As dead vegetation ages within soils, it is degraded by a combination of chemical reactions and biological processes. Soluble components of decaying vegetation may be leached out of soils and relocated by groundwater movement. Organic acids and chelating agents released by plant roots further facilitate the dissolution and hydrolysis of vegetation. Soil macrofauna, especially detritivores such as earthworms, serve to physically mix soil horizons from different depths, moving OM-rich surface leaf litter down to more water- and mineral-rich horizons and reducing the OC and nutrient content of surface soils (Bohlen et al., 2004). Detritivores also accelerate the formation and disintegration of soil carbon aggregates, resulting in overall larger aggregates of fresh (less-degraded) OM mixed to greater depth within soils (Blair et al., 1995; Cortez, 1998). This activity increases soil porosity and permeability, allowing access to oxygen to greater depth in soils to support aerobic respiration processes.

Throughout in the soils, microbial processes both positively and negatively influence soil OM degradation. Fungal hyphae and other microbial exopolymers bind soil carbon and mineral particles together into aggregates. These exopolymers add to the stock of soil OC contributed by terrestrial vegetation, and support mechanisms of physical protection of OM against further degradation; aggregate-bound OM is much less susceptible to degradation than unassociated OM (Baldock and Skjemstad, 2000). Other microorganisms participate in the degradation of soil OM as they obtain energy and cellular carbon through various metabolic processes. While aerobic respiration is confined to shallow depths of the soil where O_2 can penetrate, anaerobic processes extend throughout the soil profile, from O_2 -free microenvironments within surface soils to deeper O_2 -free soils and weathered regolith.

Soil OC degradation is limited by the availability and reactivity of both OM and electron acceptors that fuel anaerobic respiration. Sulfate is not an abundant

electron acceptor in most soils, while ferric iron and nitrate can be. Soil OM is also susceptible to degradation other than respiration. Fermentative degradation of soil OM breaks down terrestrial inputs and biopolymers into small molecules including low molecular weight organic acids, alcohols, and sugar monomers. Methanogenesis too is an important mechanism of OC degradation in soils, consuming fermentation products of such as methanol, H_2 , and acetate, sustaining the fermentative breakdown of soil OM.

Many components of soil OM are fairly susceptible to degradation and do not persist in soil environments. These include carbohydrate biopolymers (e.g., cellulose, chitin, and other polysaccharides), proteins, and nucleic acids. Other components such as lipids, lignin, and black carbon are much more resistant to degradation, and can persist for millennia as intact compounds or transitional degradation products in soils (Derenne and Largeau, 2001). Lipids commonly found preserved in soils include highly aliphatic waxes, free hydrocarbons such as *n*-alkanes and isoprenoids, and biopolymers such as cutan and suberan. Lignin is a structural biopolymer in plant cell walls that derives from condensation of phenolic precursors. Black carbon comprises a broad suite of aromatic and graphitized organic materials that form during incomplete combustion of terrestrial biomass or fossil fuels; these materials are believed to be extremely resistant to degradation (Schmidt and Noack, 2000). During degradation in soils, soil OM components are remineralized at rates depending on a complex combination of intrinsic reactivity (polymeric material being more resistant than individual monomers), physical protection, (inside mineral aggregates or encapsulated within more resistant biopolymers) and lability (proteins, nucleic acids, and carbohydrates being more reactive than lipids and lignin).

Degradation of OC in the oceans

OC occurs in both dissolved and particulate forms in the oceans. Approximately $50 \text{ Pg C year}^{-1}$ derives from marine primary production driven by phytoplankton (Field et al., 2007; Sabine et al., 2004 and references therein). Rivers deliver an estimated 0.5 Pg of OC to the oceans each year. Primary production is confined to the photic zone of the world ocean, where light and nutrients combine in sufficient abundance to support photosynthetic activity. Within and immediately below the photic zone is a zone of intense heterotrophic activity, in which grazing zooplankton and aerobic heterotrophic bacteria consume particulate OM (Lee et al., 2004). The heterotrophic activity in near-surface waters has several impacts on OC degradation in the oceans. One is that $>90\%$ of primary production is effectively remineralized in the upper 200 m of the marine water column, leaving only a small fraction of surface particulate OM for export to the deep ocean (Suess, 1980; Honjo et al., 2008). Second is that mineral ballasting (association of OM with biogenic minerals produced by plankton or with minerals delivered

from continents to the surface ocean by winds and river) increases the sinking rate of OM through the water column, reducing the time available for degradation in the ocean (Lee et al., 2004; Armstrong et al., 2002). Aggregation of particulates in surface waters results in increased particle size and sinking velocity, further accelerating the export of less-degraded particulate OM to a depth (Sheridan et al., 2002). Lastly, heterotrophic grazing of surface particulates results in net evolution of the composition of sinking particulates, as more labile or easily degraded components are consumed (Lee et al., 2004; Wakeham et al., 1997).

In living biomass of the photic zone, OM that can be identified at the molecular level comprises $>80\%$ of total OC. Between 200 and 1,000 m water depth, molecularly uncharacterized material comes to dominate total OM, such that much of the material delivered to seafloor sediments cannot be assigned to typical compound classes such as lipids, carbohydrates, and amino acids (Lee et al., 2004). Some of this relative increase in uncharacterized material may result from selective preservation of photic zone precursors, while some may be added to sinking particulates as exopolymeric material generated by heterotrophic bacteria that feed on sinking particulate matter. There are also changes observed in the molecularly characterizable fraction of sinking particulate OM. Lipids resistant to degradation, such as long-chain saturated fatty acids and alkenones, are substantially enriched in relative abundance compared with initial photic zone biomass, while pigments, many carbohydrates, and polyunsaturated fatty acids are readily lost from particulates within or below the photic zone (Lee et al., 2004).

This background picture of OC degradation is confounded by the role of mineral surfaces. Minerals, whether delivered to surface waters from the continents by winds and rivers, or produced by plankton in the water column, make up the bulk of sinking particulate mass. OM can be sorbed to mineral particles, and with their greater density, OM-associated particulates can sink rapidly through the water column, helping to export relatively undegraded OC beyond the photic zone. In this way, terrestrially derived OM, which may be protected from degradation by association with detrital minerals or OM macromolecules, can be delivered to deep sea sediments. More generally, marine OM may be protected from degradation by adsorption in mesopores of sinking mineral particles, or OM mineral aggregates taken together may resist degradation, where OM is located in interstices between the mineral grains (Hedges et al., 2001). Clearly, degradation of OM within the marine water column reflects a complex interplay of inherent resistance of various organic materials across a continuum of lability, coupled with mechanisms of both speeding the rate of sinking through the water column and increasing protection from degradation by the association of OM with biogenic and terrigenous minerals.

This discussion of heterotrophic degradation of OC applies to an oxygenated water column. In several locations around the globe, large proportions of the water column are

anoxic. These include the Black Sea, the Cariaco Basin, and seasonally in the Arabian Sea, eastern tropical North Pacific and California Borderlands Basins, among others. Lack of oxygen effectively shuts down aerobic respiration in these regions, allowing the roles of anaerobic microbial processes to dominate OC degradation. In these anoxic basins, the extents of OM degradation as a fraction of primary production are lower than in open ocean sites, leading to higher sediment OC contents. Although the rates of degradation under oxic and anoxic conditions may be similar, the overall proportion of total OM that resists degradation may be greater under anoxic conditions (Van Mooy et al., 2002).

Degradation of OC in marine sediments

Efficient heterotrophic processes in the water column mean that only a small fraction ($<1\%$) of primary production reaches the sea floor. Of this, most is degraded within the upper meters of sediment, leading to OC burial of approximately $160 \text{ Tg C year}^{-1}$ (Berner, 1989; Hedges and Keil, 1995). Clearly, a large fraction of ocean carbon inputs ($\sim 50 \text{ Pg C year}^{-1}$) is degraded in both the water column and shallow sediments.

There is a positive relationship between sediment accumulation rate (either cm year^{-1} or $\text{g}_{\text{carbon}} \text{ cm}^{-2} \text{ year}^{-1}$) and OC burial efficiency, where burial efficiency is the fraction of OC ultimately preserved at depth in sediment relative to OC delivered to the sediment-water interface (Burdige, 2007; Aller, 1998; Canfield, 1994). At very low sedimentation rates, the sediment layers are buried very slowly, and aerobic processes have ample time to remineralize the OM that is delivered to these sediments, thereby explaining the low total OC contents of many low sedimentation rate marine settings. Closer to shore as sedimentation rates increase, rapid burial means that anoxic conditions dominate at shallower sediment depths, and anaerobic degradation processes become more important. Nonetheless, sediments underlying oxygen-deficient waters do not uniformly exhibit high carbon burial efficiency, indicating that oxygen alone is not the primary driver controlling OM degradation rates (Burdige, 2007). Burial efficiencies among a range of marine sediment types range between 10% and 20%. Thus, very little primary production escapes degradation processes to become incorporated into the sedimentary record.

Controls on OC degradation in sediment are similar to those operating in soils and in the marine water column: selective degradation of inherently resistant components, physical protection through association with mineral or organic polymeric surfaces, and availability of electron acceptors and/or appropriate substrates for nonrespiration degradation processes such as fermentation and methanogenesis (Burdige, 2007). Oxygen does not limit OC degradation. Most marine sediments are anoxic within centimeters of the sediment-water interface. Denitrification, sulfate-, iron- and manganese-reduction, fermentation, and methanogenesis are all active components of OM degradation. Oxygen exposure time is nonetheless

a useful proxy for understanding the extent of OC degradation from one environment to the other. Longer cumulative oxygen exposure times result in more OC degradation in sediment and overall lower OM burial efficiency (Aller, 1998; Hartnett et al., 1998).

Most OC is buried in shallow, continental margin sediments. These environments have been targets of numerous investigations over the years, and have provided insights into OC degradation processes in the uppermost few meters of buried sediments (see Martens et al., 1992). Deeply buried marine sediment such as from the Woodlark Basin and Peru Margin in turn demonstrate microbial activity hundreds of meters deep in sediments, indicating OC degradation can persist at slow rates for geologic spans of time (D'Hondt et al., 2004; Wellsbury et al., 2002).

Degradation of OC in ancient sedimentary rocks

The single largest pool of OC on the Earth (15 million Pg C) is represented by OM contained in ancient sedimentary rocks, a mass that dwarfs all other pools of OC combined (Field et al., 2007; Sabine et al., 2004). Traditionally, OC in sedimentary rocks has been viewed as resistant to degradation other than high temperature oil and gas generation or graphitization. Degradation can occur where sedimentary rocks are exposed at the Earth's surface through erosion and soil formation (Petsch et al., 2000, 2001). One unexpected theme emerging from this work is that OC degradation during rock weathering is not completely efficient. Highly aged OC is detected in river particulates from watersheds draining sedimentary lithologies (Longworth et al., 2007; Goni et al., 2005; Blair et al., 2003; Leithold et al., 2006).

However, very little of the total pool of sedimentary OM is exposed in the Earth surface environments; most remains deeply buried in the Earth's crust for millions of years. The persistence of OC in sedimentary rocks for long expanses of geologic time, and its preservation up to the present day, would suggest that degradation processes must largely cease after the burial of OM in sediments. Yet, microbial degradation of deeply buried OM has been described in a number of subsurface environments. These include clear signatures of hydrocarbon biodegradation in many petroleum systems (Head et al., 2003, 2006; Jones et al., 2008) and OM-rich sedimentary rocks (Formolo et al., 2008), coupled with molecular biological analyses that support an interpretation of an active subsurface biosphere involved in OC degradation (Waldron et al., 2007; Jones et al., 2008). These subsurface OC degradation processes are particularly valued for their role in natural gas generation in petroleum systems and other sedimentary basins.

Summary

OC degradation represents the suite of processes by which OM is transformed and remineralized, mainly through biological activity, within soils, aquatic systems,

sediments, and sedimentary rocks. The diverse forms and compositions of natural OM result in a wide range of rates of degradation, as some components are inherently resistant to degradation while others are labile and are thus quickly consumed following biosynthesis. The inherent resistance of some components of OM results in selective preservation in soils and sediments. This selective preservation is attenuated by mechanisms of physical protection, either by association with mineral surface or encapsulation of labile components within more recalcitrant organic matrices. In this way, nominally labile OC can be preserved for greater extents of time or transported across longer distances than would otherwise be the case. Future investigations of OC degradation will likely focus on (1) improved construction of carbon budgets for soils, the oceans, and sediments; (2) the mechanism(s) by which certain compound classes and organic materials remain resistant to biological degradation; (3) improved understanding of the association of organic materials with mineral surfaces, their selective adsorption/desorption behavior, and the physical scale of these relationships; (4) the roles that terrestrial inputs of OM to marine sediments and recycling of ancient OM during rock weathering play in controlling the overall reactivity and preservation of OC in sediments; and (5) improved understanding of couplings between OM composition and degradation processes active within deep subsurface sedimentary environments.

CARBONATE ENVIRONMENTS

Eberhard Gischler

J.W. Goethe-Universität, Frankfurt am Main, Germany

Definition

Carbonate environments occur both in the terrestrial and marine realms as well as in transitional zones between the land and the sea. The variety of environments spans from high-elevation continental lakes to the deep sea, from the equator to latitudes of about 60°, and they include dry and wet climate realms. The majority of carbonates are produced in the sea, currently in more or less similar proportions in neritic and pelagic settings. Carbonate production is to a large part a consequence of biological activity, either directly as in shell and skeleton formation or indirectly as a result of metabolic reactions, which trigger precipitation. The highest rates of carbonate production per unit time and space are probably reached in tropical coral reefs where several kilograms of calcium carbonate form on 1 m² during 1 year's time.

Introduction

Modern carbonate sediments are largely a product of biologic activity, either enzymatically controlled like in calcium carbonate (CaCO₃) shell and skeleton formation of aquatic organisms or indirectly by the metabolic activity

of organisms, which change water chemistry so that carbonate precipitation is enhanced (Milliman, 1974; Scholle et al., 1983; Scoffin, 1987; Tucker and Wright, 1990; Flügel, 2004; Schlager, 2005). The former refers to common carbonate producers such as corals, mollusks, calcareous algae, brachiopods, bryozoa, echinoderms, sponges, foraminifera, or coccolithophorids. The latter includes microbes and algae, which are of great importance in the formation of microbialites (stromatolites and thrombolites), tufa, in the initiation of carbonate precipitation, e.g., by removing carbon dioxide (CO_2) during photosynthesis, or as photosymbionts in reef corals, larger benthic foraminifera, giant clams, and sponges (Figure 1).

Possible exceptions of biologic production of carbonate include some carbonate muds and non-skeletal carbonate particles such as ooids, peloids, and aggregate grains that are currently forming in the Bahama Banks, the Persian Gulf, restricted platforms, or certain lakes. Peloids include both cemented fecal pellets as well as micritized or recrystallized skeletal grains (Purdy, 1968). Recrystallization is a common pattern in carbonate sediments and rocks, which is a geologically fast process (Bathurst, 1971; Reid and Macintyre, 1998). Carbonate cements are another common phenomenon in which biogenic *versus* abiogenic precipitation is discussed (Schneidermann and Harris, 1985; Schlager, 2005). Classic examples of relatively fast and abundant carbonate cementation include tropical coral reef frameworks (Grammer et al., 1993) and beachrock (Gischler, 2007).

The majority of carbonate sediments by far are produced in the sea. Presently, about half of this carbonate originates in the pelagic realm and largely includes shells of planktonic and benthic foraminifera, pteropod mollusks, and coccolithophorids. The other half is produced in the neritic realm by corals, mollusks, calcareous algae, brachiopods, bryozoa, and echinoderms. It is estimated that this 50:50 ratio between pelagic and neritic carbonate sedimentation changed to 90:10 during Quaternary lowstands of sea level (Milliman and Droxler, 1996).

Carbonate Environments, Figure 1 Carbonate formation in terrestrial, transitional, and marine environments. (Modified from Schlager 2005.)

Today, carbonate minerals commonly formed in the sea are aragonite and high-magnesium calcite (calcite with 4–21% MgCO_3). After sodium (Na^+), magnesium (Mg^{2+}) (1,300 ppm) and calcium (Ca^{2+}) (410 ppm) are the second and third most common cations in the ocean, respectively. Carbonate as HCO_3^- is the third most common anion (140 ppm) after chloride (Cl^-) and sulphate (SO_4^{2-}). Calcium carbonate is precipitated after the formula:

In freshwater environments, for comparison, where ion concentrations in general and the magnesium/calcium ratio in particular are much lower, low-magnesium calcite typically is precipitated. Subaerial exposure surfaces of limestone are characterized by dissolution, and form typical karst features.

Dolomite ($\text{MgCa}(\text{CO}_3)_2$) may form in limited quantity both in the ocean and in lakes. Preconditions for dolomite precipitation are a high Mg/Ca-ratio and elevated salinity. Modern examples of dolomite formation include the deep sea, certain lakes, and sabkhas, which are intertidal carbonate areas in an arid climate. The majority of dolomite presently exposed on the earth's surface, however, was formed secondarily in the burial environment, by dolomitization of carbonate rocks from magnesium-rich solutions.

The analysis of non-skeletal grains such as ooids and cements throughout the marine geologic record has revealed that the mineralogy of precipitated carbonate has changed between aragonite/high-magnesium calcite and low-magnesium calcite (Sandberg, 1983). This observation, known as the Sandberg-Cycles, is a consequence of changing Mg/Ca-ratios in the ocean as controlled by plate tectonic activity. When lower spreading-rates, colder climate, and lower sea levels are experienced during the periods such as today's or the late Paleozoic icehouse worlds, aragonite predominates over low-magnesium calcite (high Mg/Ca). When spreading-rates and sea level were high and the climate was warm, such as during Devonian or Cretaceous greenhouse worlds, low-magnesium calcite precipitation was favored (low Mg/Ca). Meanwhile, additional fossil and aquarium studies have shown that quite a number of carbonate-producing organisms also change their skeleton or shell mineralogy according to Mg/Ca-ratios of seawater (Stanley and Hardie, 1998). Investigations in Precambrian carbonate rocks have supported the contention that carbonate concentrations in the ocean also fluctuated during Earth history, thereby influencing carbonate deposition (Knoll et al., 1993). In the Proterozoic, carbonate concentrations were so high that in places cements were physicochemically precipitated on the seafloor. Carbonate concentrations decreased in the Cambrian when shell and skeleton production exploded. Carbonate concentrations presumably sank again in the Mesozoic when calcareous plankton such as planctonic foraminifera and coccolithophorids

evolved. The Soda Ocean model of Kempe and Degens (1985) speculates that calcium concentrations in the ocean also dramatically decreased with shell and skeleton evolution during the end of the Precambrian through the Cambrian. These authors interpreted shell and skeleton formation as calcium expelling as a consequence of cell poisoning.

In the following, highlights of typical carbonate environments are discussed in a cross section going from the terrestrial, coast, and shallow marine to deep marine settings (Figure 2).

Terrestrial environments

Springs

Carbonate deposits are normally very rare in running freshwater because of the low ion contents of the water. Turbulence that causes CO_2 degassing may lead to

low-magnesium calcite precipitation. Also, pressure release or cooling of hot waters at springs may bring about calcite precipitation. The limestone product is usually termed tufa, which forms under ambient temperatures and may contain calcified remains of bacteria, algae, and plants (Chafetz and Folk, 1984; Ford and Pedley, 1996). Travertine, which forms in hot water (hydrothermally), is dense, usually clearly laminated, and largely lacks algae and plant remains. Typical morphologies of tufa deposits include barrages, cascades, or terraces with pools. Ooids may form in pools that hold water. Tufa deposits are restricted to the late Cenozoic, which presumably is a consequence of limited preservation potential (Figure 3).

Lakes

Lacustrine carbonates occur in both freshwater and saline lake environments (Matter and Tucker, 1978; Hakanson

Carbonate Environments, Figure 2 Carbonate environments in a land-to-sea cross section. (Modified from Flügel, 2004.)

Carbonate Environments, Figure 3 Photo of sliced Quaternary tufa deposit on Casino building of Goethe University, Frankfurt, Germany, with microbial lamination and calcified remains of algal thalli.

and Jansson, 1983; Anadon et al., 1991). Freshwater lakes in humid climates such as Lake Constance, Germany, Lake Zurich, Switzerland, or Green Lake in North America are usually perennial. Their size can be as small as $<10 \text{ km}^2$ as in Green Lake to more than 500 km^2 as in the example of Lake Constance. They are characterized by fine-grained carbonate deposits, usually in an annually laminated fashion (Figure 4). Fine-grained siliciclastics are more common during winter. Low-magnesium calcite is precipitated preferentially during warm summer months, enhanced by photosynthetic activity of phytoplankton that withdraws CO_2 . Other carbonate producers are usually ostracods, gastropods, pelecypods, and the charophytic alga *Chara*. The thalli of this alga may calcify and form characteristic tubes. Reproductive cells

(oogonia) are calcified also. Diatoms occur as well. In the case of high carbonate content of the lake water, microbial activity may occur and produce stromatolites, thrombolites, and/or oncolites (Figure 5).

Saline lakes in arid climates such as the Great Salt Lake in North America or the Dead Sea have considerable sizes of 4,400 and 600 km^2 , respectively. Saline lakes are often ephemeral. They are also characterized by abundant carbonate deposition. Controlled by the Mg/Ca-ratio, either low-magnesium calcite, high-magnesium calcite, aragonite, magnesite (MgCO_3), or dolomite is precipitated. Under high evaporation rates, sulphates and chlorides such as gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and halite (NaCl) may form. In the case of the Great Salt Lake, aragonitic ooids occur in abundance in shallow areas along shore. Also, microbial buildups and sheets are found, which are to large parts due to cyanobacterial activity. Along shore of saline lakes, caliche may be common due to fluctuating lake levels that expose larger areas. When springs are present, tufa or travertine is formed as sheets, mounds, and towers. The latter is characteristic of Mono Lake in California where spectacular towers of tufa are found.

Carbonate Environments, Figure 4 Photo of annually layered Holocene lake sediment from core, Lake Zurich, Switzerland. Light layer is carbonate; dark layer is siliciclastics. Thicker gray bed is a turbidite. Scale in centimeters. (Photo courtesy of Flavio Anselmetti.)

Subaerial exposure

Subaerial exposure of limestone leads to dissolution by meteoric waters. Typical landforms that may have considerable relief are termed karst (James and Choquette, 1988). Landforms include dolines, towers, karren, or poljes. Dissolution may produce cavities and larger caves. Calcium carbonate is re-precipitated in limestone caves in the form of speleothems such as stalactites and stalagmites. Cave pearls or pisoids (“diagenetic ooids”) may form in ponds. Residues of dissolution together with organic material may later become soils on limestone such as laterite or terra rossa. In warm and/or arid regions, carbonate-rich soils form deposits that are called caliche or calcrete (Wright and Tucker, 1991). A caliche is characterized by patterns such as brecciation, clotted textures, root holes or rhizoids, and low-magnesium calcite cements, sometimes in a needle fiber texture (“whiskers”). Laminated soilstone crusts are a special case of calcrete that can resemble stromatolitic formations. Soilstone crusts form by precipitation of calcium carbonate from evaporating pore water. The identification of subaerial exposure surfaces in the fossil record is of great importance, e.g., for the reconstruction of fluctuations in sea level and for sequence stratigraphy (Figures 6 and 7).

Transitional environments

Beaches and shores

Carbonate beaches are usually formed by sand-sized particles that originate from the adjacent shallow seabed (Inden and Moore, 1983). Shells and skeletons of organisms as well as non-skeletal grains occur. Beach zones include the shoreface, the foreshore, and the backshore. The shoreface lies below the lower tide level and is characterized by cross-bedding. The foreshore is situated between

Carbonate Environments, Figure 5 Photo of lacustrine stromatolites, Bacalar, Yucatan Peninsula, Mexico.

Carbonate Environments, Figure 6 Scheme of karst profiles in various climates. (From James and Choquette, 1988; with permission of Springer, NY.)

low- and high-tide levels. The backshore lies above the high-tide level. Sediments of the foreshore and backshore zones exhibit parallel lamination and beds dip gently toward the sea (Figure 8).

A striking feature in the tropical/subtropical realm, and common in latitudes up to 60° , is beachrock. Beachrock forms in the intertidal zone by rapid cementation of sedimentary particles by marine aragonite and high-magnesium calcite cements. The formation of beachrock is not fully understood, and is assigned to physicochemical and/or biological processes (Gischler, 2007). The strictly intertidal position of beachrock supports the contention that cements precipitate from evaporating pore water during low tide. Also, beachrock appears to be common in windward and rather exposed sites indicating that

flushing of pores by water rich in calcium carbonate is of importance. Typical sediment structures of beachrock are seaward dipping beds. Keystone vugs are small cavities in beaches and beachrock that are produced when air escapes from the beach (Figure 9).

Behind the backshore, in the landward direction, dunes may occur that are a product of eolian deposition (Abegg et al., 2001). Carbonate eolianites are common behind carbonate beaches, and are found in abundance along the eastern coast of the Yucatan Peninsula, on the islands of the Bahamas and Bermuda, along the Trucial Coast (southern Persian Gulf), and on the Balearic Islands in the Mediterranean Sea. High angle cross-bedding as well as rhizoids and caliche, indications of the meteoric realm, are characteristic. *Microcodium* are small spherical bodies

Carbonate Environments, Figure 7 Hand specimen of caliche with laminated crust. Miami Limestone from the Everglades, Florida.

of radiating calcite that forms among rhizoids in eolianites. Carbonate cements include meteoric types composed of low-magnesium calcite.

Tidal flats

As indicated by the name, tidal flats are broad and low-relief areas, which are usually flooded during high tide and subaerially exposed during low tide (Ginsburg, 1975). Classic modern carbonate-dominated examples include the humid tidal flats west of Andros Island on Great Bahama Bank (Shinn et al., 1969) and the arid examples on the southwestern side of the Persian Gulf (Kendall and Skipwith, 1969). Tidal flats are dissected by tidal channels, which are lined by levees. Levees usually enclose low-relief ponds. Beach ridges form the transition to the adjacent subtidal realm. In the case of humid tidal flats, algae such as *Batophora* and microbial mats as well as mangroves thrive along the channels and further inland in the so-called marsh. In the Bahamas, microbial mats are largely formed by the genera *Scytonema* and *Schizothrix*. Gastropods of the genus *Batillaria* occur in great abundance. Benthic foraminifera are present. In arid tidal flats or sabkhas, which transition into the desert on the landward side, microbial mats occur along channels. Also, burrows of crabs may be abundant along the channels. Nebkhas are small mounds that are produced by halophile plants that baffle sediment around their roots (Figure 10).

Sediments on tidal flats are usually poorly sorted muds, silts, and sands. They are horizontally layered and are largely derived during storms from the adjacent seabed, from precipitation, or from eolian transport. Fine-grained sediment is usually found in ponds. Mud cracks and

wrinkled, dried-out, and curled microbial mats are a typical phenomenon. Sands make up levees and beach ridges. A characteristic sedimentary structure is the bird's eyes structure, millimeter-sized fenestral pores that result from gas-bubble formation. In the fossil record, these structures are good indicators of the intertidal and shallow subtidal realm. As a consequence of evaporation on tidal flats, cemented carbonate crusts are formed that may contain dolomite. In the arid realm, gypsum and/or anhydrite is precipitated within the sediment and forms nodules, enterolithid folds, discs, and chicken-wire textures (Figure 11).

Marine environments

Carbonate shelves and platforms (Figure 12)

Restricted shelves and platforms

These carbonate environments are shallow (0–20 m) and characterized by partial or complete enclosure by islands, reefs, or shoals. Modern examples include Florida Bay (Ginsburg, 1956; Stockman et al., 1967), the Gulf of Batabano (Hoskins, 1964), Cuba, or Shark Bay, western Australia (Logan et al., 1974). The partial or complete enclosure of these platforms results in restricted circulation and in elevated water temperature and salinity. This in turn leads to low diversity biota of mollusks, benthic foraminifera, crustaceans, and echinoderms. Burrowing crustaceans (*Callianassa*) are responsible for abundant bioturbation (Figure 13). Tolerant corals such as *Solenastrea* and *Siderastrea* are occasionally found in Florida Bay. Sea grasses (*Thalassia*, *Syringodium*, *Posidonia*, and *Cymodocea*) are common, which act as bafflers of sediment. In Florida Bay, the codiacean algae *Penicillus* and *Halimeda* occur in great abundance. Dasycladacean algae such as *Acetabularia* are common. In Shark Bay, stromatolites thrive in intertidal and subtidal areas. Their abundance is classically explained by the exclusion of grazers due to the high salinities in the bay.

Sediments in Florida Bay are largely of skeletal origin. Dominant carbonate producers are mollusks, foraminifera, and the alga *Penicillus*, which is the most important source of aragonite mud (Stockman et al., 1967). Mud banks, elongated hillock-type accumulations of mud, are densely covered by sea grass (Bosence, 1995). Both skeletal (mollusk, foraminifera) and non-skeletal (peloidal) grain types are found in the Gulf of Batabano. Likewise, Shark Bay sediments include skeletal grains of mollusks and foraminifera as well as mud from the breakdown of *Penicillus*. Non-skeletal grains include ooids that are formed in shallow areas, peloids, and reworked lithoclasts from underlying Pleistocene limestone (Figures 14–16).

Open-rimmed shelves and platforms

Intensively studied examples of rimmed carbonate shelves and platforms include the Florida Reef Tract, the Belize shelf and barrier reef, Central America, and the Queensland shelf and Great Barrier Reef, NE Australia. These environments are largely characterized by normal marine

Carbonate Environments, Figure 8 Scheme of beach zonation and sediments. (From Inden and Moore, 1983; with permission of American Association of Petroleum Geologists.) HWM: high water mark; LWM: low water mark.

conditions. Water depths range from 0 to 200 m. The areas covered are several 1,000 km² to several 100,000 km² in the case of the Queensland shelf. In between the coast and platform margins, low and high islands as well as patch reefs and faroes (small circular lagoon reefs) of coral can be found.

Carbonate sediments on these rimmed platforms are almost exclusively of skeletal origin and facies belts more or less parallel to the coast (Ginsburg, 1956; Maxwell, 1968; Purdy and Gischler, 2003; Purdy et al., 2003). On the Belize and Queensland shelves, siliciclastics derived from the hinterland mix with carbonate sediment. As

Carbonate Environments, Figure 9 Tropical beach with beachrock outcrop. Loggerhead Key, Dry Tortugas, South Florida.

a consequence, facies are siliciclastics-dominated near the coast. Marls are found in the middle shelf. Largely carbonate sediments occur at the outer platform and platform margins. Central shelf marls are rich in fragments of mollusks and foraminifera. Mud content is high. In Belize and NE Australia, pelagic biota such as pteropods and planktonic foraminifera, respectively, are found in these platform areas due to the high depths of the shelves. Shelf reefs and outer platforms and margins are predominated by mostly coarse-grained sediments rich in coral, coralline red algae, *Halimeda*, and benthic foraminifera (Figure 17).

Platform margins are several kilometers wide and water depths are between 0 and 50 m. Coral reefs are widespread with the common genera *Acropora*, *Porites*, *Montastraea*, *Diploria*, *Platygyra*, *Pocillopora*, and *Millepora*. The reef crest proper is at sea level. The shallow forereef slope is often characterized by spur-and-groove systems (Shinn et al., 1981) (Figure 18). In the case of Belize, a steep sometimes vertical slope occurs in the deep forereef. This bypass margin was investigated in detail by James and Ginsburg (1979). The Florida and Queensland margins with lower angles are examples of depositional margins (Read, 1985).

Isolated platforms

The largest known isolated carbonate platforms include the Bahamas in the Atlantic and Great Chagos Bank in the Indian Ocean, which each cover 10,000 to 100,000 km², respectively. In the Bahamas archipelago, Great Bahama Bank (Purdy, 1963; Ginsburg, 2001) is probably the best known example (Figure 19). Great Bahama Bank is a shallow, low-relief submarine bank,

which is surrounded by deep water. Water depths on the bank only rarely exceed 6 m. The bank has very high and steep bypass margins, especially on the eastern side. The steepness is presumably the result of both biological construction and erosion. On the eastern side, a well-developed coral reef rim with abundant *Acropora* exists in shallow water. Otherwise, the margins of Great Bahama Bank are largely predominated by ooid sand shoals. These shoals are very shallow, high-energy environments where ooids form and are moving in the form of up to several kilometer-long rippled sand waves, more or less parallel to the bank margins. Joulter Cays ooid shoal in the northeastern corner of the bank is intensively studied (Harris, 1979). The western bank margin also has long and wide ooid shoals. Near the southern end of Tongue of the Ocean, ooid sand waves are oriented perpendicular to the bank margin. The eastern interior part of Great Bahama Bank is covered by the Pleistocene island of Andros, which gets as high as 30 m above present sea level. Most of the platform interior is covered by shallow water as mentioned above. Benthic marine animals such as gastropods (*Strombus*) and echinoids (*Oreaster*) are rather rare. Codiacean algae such as *Penicillus* and sea grass (*Thalassia*) are common. Salinities are above normal marine on the bank and may reach 45‰ close to Andros Island. Sediments are mostly non-skeletal and include peloidal muds as well as aggregate grain ("grapestone") and peloidal sands (Purdy, 1963). Skeletal sands only occur around the eastern reefal margin and in a small band on the western margin.

The origin of carbonate mud on Great Bahama Bank is a matter of debate since several decades [see discussion in

Carbonate Environments, Figure 10 Photos from tidal flats. (a) Aerial view of western part of Andros Island, Bahamas. (Photo courtesy of Robert Ginsburg.) (b) Microbial mat on sabkha in Khiran, southern Kuwait.

Gischler and Zingeler (2002)]. Mud largely consists of micron-sized aragonite needles. It potentially originates from codiacean algae such as *Penicillus*, from physico-chemical precipitation in the warm and saline surface waters of the bank, or from biologically (bacterially) induced precipitation of calcium carbonate. Commonly occurring clouds of suspensions of carbonate mud and water on the bank, known as “whittings,” have been described as expressions of spontaneous precipitation phenomena. However, there is also evidence that whittings are simply a consequence of bottom sediment stirring either by fish or by currents.

More than 2 m high subtidal stromatolites were discovered by Dill et al. (1986) on the Bahamas in normal marine seawater near the Exuma islands. Previously, only small microbial buildups were known from the Bahamas. These stromatolites develop within very strong currents and significant bottom sediment movement. Apparently sediment movement largely excludes grazers and triggers carbonate accumulation via trapping and binding.

Seismic profiling and deep drilling has revealed that the geologic history of Great Bahama Bank was not simply a process of aggradation (Ginsburg, 2001). A complex interplay of slow subsidence and sea-level change has

Carbonate Environments, Figure 11 Tidal flat scheme from Andros Island, Bahamas. (From Scoffin, 1987; with permission of Blackie and Son Ltd.)

modified the bank during the Neogene in that shallow water banks repeatedly aggraded, backstepped, and prograded, thereby filling deep seaways and moving the western margin of Great Bahama Bank by 30 km to the west into the Straits of Florida.

Carbonate ramps

The term ramp was introduced to the carbonate literature for unrimmed carbonate shelves with a low-angle dip ($<1^\circ$) toward the open sea (Burchette and Wright, 1992; Wright and Burchette, 1998). The classical modern example is the southwestern Persian Gulf. Other modern ramp examples include the western Florida margin or Campeche Bank, Mexico. Geometrically, there are homoclinal and distally steepened ramps (Figure 20). Depositional environments are usually divided into inner, middle, and outer ramps. The inner ramp environment is above fair-weather wave base (FWWB); the mid-ramp between FWWB, and

the storm wave base (SWB); the outer ramp below SWB. In the southern Gulf, inner ramp environments consist of shoals and barrier facies with ooid-skeletal sands. Smaller reefs are found just seaward of the barriers. Back barrier sediments are usually fine-grained peloidal and mollusk muds and sands. Mollusk-rich silts and sands are common on the mid-ramp. Outer ramps are characterized by carbonate and argillaceous muds ("marl") with abundant mollusks. In the northern Gulf, barriers are largely lacking. In contrast to the southern Gulf, which is tide-dominated, the northern Persian Gulf ramp is largely wave-dominated. On the inner ramp, quartz grains derived from the adjacent mainland desert may be present in addition to ooid shoals. Small coral patch reefs may also be found in the inner ramp zone. Mid-ramp and outer ramp deposits are also dominated by mollusk-rich silts and sand and argillaceous muds, respectively. Pinnacle-type patch reefs of coral occur in the outer ramp.

Characteristic storm beds or tempestites in mid-ramp settings were identified by Aigner (1982) in the European Triassic Muschelkalk beds. Tempestites exhibit characteristics such as sharp bases, sole marks, graded bedding, hummocky cross-stratification, and ripple marks. Because there are no larger outcrops in modern ramps and shelves showing complete sedimentary bodies or large-scale sedimentary structures, our knowledge of storm beds is largely based on the fossil record.

Temperate- and cool-water shelves and platforms

Apart from the abundant typical warm water and low latitude deposits, about one third of the modern carbonate

Carbonate Environments, Figure 12 Scheme of carbonate platform types and morphologies. (Modified from Tucker and Wright, 1990.)

shelves and platforms are characterized by temperate and cool-water carbonate sedimentation (Lees and Buller, 1972; James and Clarke, 1997). Prominent and well-studied modern examples are the Great Australian Bight or the Mediterranean realm. Temperatures in the cool-water realm are below 20°C and heterotrophic carbonate producers predominate. They include mollusks, echinoderms, bryozoa, foraminifera, coralline algae, barnacles, and serpulids ("heterozoan association"). Constituent carbonate particles of the same taxa are also present in warm-water carbonates; however, there, they are swamped by carbonate grains from rapidly growing producers that have photosymbionts such as corals and codiacean algae as well as by mud and non-skeletal carbonate formation as in ooids, peloids, and cements ("photozoan association"). There are also cases where heterozoan carbonates occur in warm-water settings, e.g., in western Florida or to some degree on Campeche Bank, Mexico, as well as in several fossil examples. Elevated nutrient contents and primary production are usually responsible, and hamper abundant photozoan carbonate production (Figure 21).

Temperate and cool-water carbonates usually form unrimmed shelves or platforms, and they are strongly influenced by hydrodynamic energy. Submarine cementation is rather weak. In modern examples, kelp (brown algae) forests occur in the constantly wave-dominated inner ramp. Siliciclastic sediment may derive from local sources from the mainland. Sand waves and dunes are found on the mid-ramp, which is prone to storm-reworking. Sediments on inner and mid-ramps are mostly coarse-grained and frequently redeposited. The outer ramp environment may contain fine-grained sediment with bryozoan, sponge, or non-zooxanthellate coral mounds.

Carbonate Environments, Figure 14 Sediment distribution in Florida Bay and the reef tract. (Modified from Ginsburg, 1956.)

Carbonate Environments, Figure 15 SEM photo of carbonate mud from Belize with abundant aragonite needles and nanograins, which originate from codiacean algae.

Reefs

Reefs are classical objects of geobiological research because they are rock formations built by the biological activity of organisms. Reefs normally form topographic highs above the surrounding sea floor. Reef organisms

comprise large numbers of taxa, which either construct a framework or baffle and bind sediment, which is rapidly consolidated. In addition, there are reef dwellers, which do not necessarily contribute to reef growth, and, there are reef-destroying organisms, which bore into, dissolve, or

Carbonate Environments, Figure 16 Underwater photographs of calcareous codiacean algae (a) *Penicillus* and (b) *Halimeda*, Belize.

erode reef limestone. This ecological guild concept of constructors, bafflers, binders, dwellers, and destroyers was developed for reef organisms by Fagerstrom (1987), who compiled a geological history of reef building. Like Wilson (1975) before, he stressed that reef building is a geologically old phenomenon that reaches back into the Archaean, however, reef-building organisms have repeatedly changed with time. Recently, Wood (1999), Stanley (2001), and Kiessling et al. (2002) have provided additional monographs and editions on the long history of reef building. The most abundant groups of reef builders during earth history have been microbes, corals, sponges, bryozoa, and rudist bivalves. Reef destroyers include boring sponges, bivalves, worms, and microborers as well as grazing gastropods, echinoderms, and fish. Reef building

is a complex interplay of reef construction, destruction, sedimentation, and cementation, processes which occur at the same time and eventually produce what geoscientists would term reef limestone (Scoffin, 1992) (Figure 22).

Tropical reefs

Modern tropical reefs cover an area of about 600,000 km² in tropical-subtropical latitudes around the globe. Reefs thrive in warm waters between 18 and 30°C, normal marine salinity, and clear and oligotrophic waters. They represent the most diverse marine ecosystem with several tens of thousand of species including taxa from all known animal phyla. Scleractinian corals and red coralline algae are the dominant builders (Figure 23). Other calcareous

Carbonate Environments, Figure 17 Carbonate sediment distribution on the Belize shelf and platforms. (With permission of Purdy and Gischler, 2003.)

Carbonate Environments, Figure 18 Aerial photograph of zoned margin in Lighthouse Reef, Belize.

algae such as codiaceans, mollusks, benthic foraminifera, and echinoderms are important sediment producers on tropical reefs. Reef-building Scleractinian corals live in symbiosis with dinoflagellates (“zooxanthellae”), which live in their tissues and photosynthesize. The symbionts are both important for the coral metabolism by providing food and also enhance skeletal growth of the aragonite coral skeleton because they consume carbon dioxide.

Because of the symbiosis, the tops of tropical reefs are at or close to sea level. Fossil coral reefs are therefore used as gauges for past sea levels. The annual banding of coral skeletons and the longevity of colonial reef corals makes them ideal archives of historical climate change (“sclerochronology”).

Since Darwin (1842), tropical reefs are morphologically subdivided into fringing reefs, barrier reefs, and atolls. Fringing reefs occur close to the coast with a shallow moat or lagoon in between reef and coastline. These reefs are abundant in the Caribbean Sea and the Indonesian archipelago. Barrier reefs are larger structures that are separated from the coast by a deep channel, like in northeastern Australia, New Caledonia, or Belize. The Great Barrier Reef is the longest barrier reef with more than 2,000 km in length. Barrier reefs in the sense of Darwin surround volcanic islands like, e.g., Bora Bora in the Tuamotu archipelago. Atolls are circular reefs, which enclose a deep lagoon. There are about 400 atolls worldwide. They are most common in the Pacific and Indian

Oceans, and have a volcanic basement. According to Darwin’s (1842) elegant subsidence theory, fringing reef, barrier reef, and atoll are genetically connected by the simple process of subsidence of a volcanic island. Tayama (1952) carried the theory even further and explained the formation of small circular reefs with shallow or filled lagoons, so-called table reefs, as the final stage in reef development before drowning and seamount (guyot) formation. Even so, the subsidence theory does not explain large barrier reefs that are attached to large continental land masses, and, it neglects the significance of eustatic sea-level change, which was first considered in Daly’s (1910) glacial control theory. Indeed, drilling on Enewetak Atoll in the 1950s has demonstrated about 1.3 km of shallow-water reef limestone on top of an Eocene volcano, but numerous hiatuses were found, which are the result of repeated subaerial exposure. The antecedent karst model of Purdy (1974) takes into account the importance of limestone dissolution by meteoric waters during eustatic lowstands of sea level, which are even able to produce fringing, barrier, and atoll reef morphologies as well as spur-and-groove patterns in subaerially exposed limestone and limestone-volcanic islands. Recent studies have shown that modern barrier reefs are comparably young features that only came into existence about 400–600 ky ago when high amplitude, eccentricity-driven eustatic sea-level changes became more and more dominant (International Consortium of Great Barrier Reef Drilling, 2001; Multer et al., 2002).

Tropical reefs are characterized by ecological zonation, with zones running more or less parallel to bathymetry (see Figure 18). Modern reefs also exhibit provincialism between Atlantic and Indo-Pacific realms. For high sea-level greenhouse climates in earth history, like in the Devonian or Jurassic and Cretaceous, however, no evidence of provincialism was found. Common reef zones include from outboard to inboard the fore reef, reef crest, back reef, sand apron, and lagoon. Surface sediments are coarse sands of coral and calcareous algae in reefal environments and more fine-grained, mollusk- and foraminifer-rich sediments in lagoonal areas. Several shallow lagoons of Caribbean reefs are rich in non-skeletal grains. Milliman (1974) explained this difference to Indo-Pacific reefs, which he termed the “ooid problem,” by the shallower and smaller lagoons, in which water exchange is much faster. Carbonate-rich water circulates more rapidly and thereby preferentially produces non-skeletal grains such as ooids, peloids, and aggregates by submarine cementation (Figure 24). However, the discovery of abundant modern non-skeletal grains such as ooids and cemented fecal pellets in the shallow lagoons of Aitutaki Atoll (Cook Islands) and Bora Bora (Tuamotus) in the south Pacific opposes this widely held concept (Rankey and Reeder 2009; Gischler 2010).

Drilling in the barrier reef around the island of Tahiti (Montaggioni and Camoin, 1993) and investigations in cavities of the Great Barrier Reef (Reitner, 1993) have shown the importance of abundant microbial activity in

Carbonate Environments, Figure 19 Sediment map of the Great Bahama Bank. (With permission of Traverse and Ginsburg, 1966.) Bank margin is defined by 600 ft (180 m) depth contour.

tropical coral reef cavities. Especially in Tahiti, stromatolite-type formations are quite abundant, even though microbial activity was apparently most widespread during the early Holocene. In the Great Barrier Reef example, sponges and sponge tissue decay are additional agents besides microbes that trigger carbonate formation.

Deep- and cold-water reefs and mounds

After the first discovery of abundant coral reefs in deep and cold water off the Scandinavian coast (Teichert, 1958), it took several decades before these reef structures were investigated in great detail (Freiwald and Roberts, 2005; Roberts et al., 2006). These reefs are largely built by non-zooxanthellate branched corals such as *Lophelia*, *Madrepora*, or *Cladocora* in water depths below 200 m and temperatures between 4 and 2°C. Reef thickness may reach more than 30 m and individual reef structures have lengths of more than 10 km. Species richness in the

north Atlantic examples is around 1,300 taxa. Deep-water reef foundations are usually submarine topographic highs such as, e.g., iceberg plough marks. Meanwhile, it has become clear that deep- and cold-water reefs in the northeastern Atlantic are not restricted to the Scandinavian area but are also abundant off the Atlantic shelf margin as far south as the Mediterranean and in the Caribbean.

Somewhat similar deep- and cold-water reefs, termed lithoherms, were discovered in strong currents at the bottom of the Straits of Florida in 600–700 m of water (Neumann et al., 1977). Lithoherms are several 100 m long and up to 50 m high. Their shape is ellipsoidal with the long axis parallel to the current. The faunal elements mainly include non-zooxanthellate corals, crinoids, sponges, and bryozoa. Interstitial muddy to sandy detrital carbonate sediment is abundant and largely a product of baffling. The mounds are cemented at the surface in that concentric, hard carbonate crusts occur. Stromatactis-type fenestral

Carbonate Environments, Figure 20 Scheme of a ramp. (Modified from Burchette and Wright, 1992.)

Carbonate Environments, Figure 21 Scheme of cool-water shelves. (Modified from James and Clarke, 1997.)

cavities were discovered and attributed largely to burrowing and subsequent sediment infill.

It is tempting to interpret the Florida lithoherms as modern analogues of fossil deep-water mud mounds. Mud mounds are common in the fossil record, especially in the Devonian and Carboniferous (Monty et al., 1995). The most prominent examples are probably the

Carboniferous ("Waulsortian") mud mounds. Waulsortian mounds or banks also formed in deep water and contain biota with crinoids, sponges, bryozoa, brachiopods, and mollusks. Corals are rare. Stromatactis, large cement and sediment-filled fenestral cavities with flat bases and irregular tops, is very common in Paleozoic mud mounds (Krause et al., 2004). Even so, major differences between

Carbonate Environments, Figure 22 (a) Scheme of reef limestone formation with synchronous processes. (From Scoffin, 1992; with permission of Springer: Berlin, Heidelberg.) (b) Quaternary reef limestone from Belize Barrier Reef. C coral; M microbialite, D detritus.

the lithohermes and the Waulsortian mud mounds appear to be the abundance of carbonate mud in the fossil examples. Lithohermes have higher quantities of coarse sediment. Also, lithohermes are largely biodepositional mounds whereas the Waulsortian ones are microbial mounds in which in situ mud production prevailed (Monty et al., 1995).

Also, mud mounds and deep-water carbonate mounds have been found to be associated with cold seeps or hot vents (Beauchamp and von Bitter, 1992; Mounji et al., 1998). Around locations of seepage of methane (CH_4)

and hydrogen sulfide (H_2S) on the seafloor, authigenic carbonate precipitation may be triggered by bacteria via chemosynthetic processes that produce bicarbonate:

Usually, metazoans such as certain bivalve mollusks (*Caplyptogena*, *Bathymodiolus*, lucinids), vestimentiferan worms (*Riftia*), and thysanid shrimps, which have

Carbonate Environments, Figure 23 Underwater photograph of a reef with abundant acroporids and milleporids. Glovers Reef Atoll, Belize.

Carbonate Environments, Figure 24 Thin-section photographs of typical (a) skeletal carbonate sediment in beachrock with corals (light) and *Halimeda* (dark) and aragonite needle cement; (b) non-skeletal carbonate sediment with aggregate grains, ooids, and peloids. Kuwait, northern Persian Gulf.

chemosynthetic bacteria in their gills and tissue thrive at these seeps. Interestingly, fossil seeps often have abundant brachiopods (dimerelloids, e.g., *Peregrinella*), which do not have modern representatives that harbor chemosynthetic bacteria (Campbell and Bottjer, 1995). Meanwhile, fossil seep carbonates have been reported from rocks as old as Silurian (Little et al., 1997). Apart from their characteristic fauna and texture, and their patchy distribution, methane seep carbonates may be identified rather easily in the fossil record by geochemical means. Carbon isotopes of these carbonates are typically very strongly depleted (Beauchamp and von Bitter, 1992).

Slope

Carbonate slopes may have lower angles as in depositional margins or higher angles in bypass margins. In general, carbonate and siliciclastic slopes have similar heights, however, carbonate slopes are usually steeper (Schlager, 2005). James and Ginsburg (1979) have compiled slope morphologies of several western Atlantic carbonate margins, which usually exhibit a threefold division (Figure 25). There is a low-angle (20–30°) fore reef slope, a steep slope to vertical wall between ca. 50–150 m and a 50° slope below the wall, which is dominated by carbonate debris and blocks transported down from shallower depths. Foliateous corals, *Halimeda*, crinoids, and sponges may be found colonizing the walls. In general, the slope is characterized by sediment redeposition as seen, e.g., in the occurrence of talus blocks, debris-flows, and slump deposits, as well as breccias (James and Ginsburg, 1979; Schlager, 2005). Limestone turbidites (Meischner, 1964) originating from platform tops occur on lower slopes and in the adjacent

Carbonate Environments, Figure 25 (a) Schemes of fore reef slopes. (Modified from James and Ginsburg, 1979.) (b) Sedimentary processes on slopes. (From Enos and Moore, 1983; with permission of American Association of Petroleum Geologists.)

toe-of-slope among pelitic deposits. Limestone turbidites have similar characteristics as siliciclastic turbidites, with sharp bases, graded beds of debris, and lenticular geometries of individual turbidite bodies. Highstand shedding describes the fact that limestone turbidites in the Quaternary are more common during sea-level highstands when platforms are flooded and abundant carbonate produced as opposed to lowstands of sea level when platforms are subaerially exposed (Droxler and Schlager, 1985). Recent investigations in fossil slope deposits have revealed the formation of so-called auto-micrites as a result of microbial activity on carbonate slopes (Keim and Schlager, 2001). Automicrite facies is apparently a significant agent for platform margin and slope stabilization in these Triassic examples.

Basin

Basinal carbonate environments are in depths between about 200 and 5,000 m (Hsü and Jenkyns, 1974; Crevello and Harris, 1985). The basins of the Atlantic, Indian Ocean, and large parts of southern Pacific Ocean are covered by very fine-grained carbonate sediments, which are termed ooze. Consolidated ooze is called chalk. Carbonate deposition and accumulation is controlled by carbonate supply from the pelagic realm and largely includes tests of planktonic foraminifera, pteropod gastropods, and coccoliths (Figure 26). These particles are transported to the sea floor as “marine snow,” which is largely composed of fecal pellet aggregates. Fecal pellets derive from arthropods such as krill and copepods, and sinking velocities of pellets are much faster as compared to those of individual tests. Other minor contributors of calcium carbonate to the deep sea include shells of ostracods, shells of pseudoplanktonic organisms such as arthropods and bivalve mollusks, and cephalopod shells from *Nautilus*, *Sepia*, and *Spirula*. Carbonate accumulation is also dependent upon the position of the aragonite and calcite compensation depths (ACD, CCD), respectively. The ACD lies at about 2,000–2,500 m and the CCD at about 5,000–5,500 m depth. Below the CCD all calcium carbonate is dissolved. Biota in basinal environments include benthic foraminifera, echinoderms, sponges, and crustaceans. Ichnospecies are *Planolites*, *Chondrites*, and *Zoophycos*. *Thalassinoides*-type bioturbation, often filled by chert, is typical in Cretaceous deep-water limestone. Except for fine lamination, sedimentary structures are usually rare. In Quaternary deposits, carbonate cycles were discovered, which are caused by changing carbonate saturation states during glacial and interglacials. During glacial, lower sea-level positions result in higher carbonate saturation in the pelagic realm, because the neritic carbonate factory is largely shut off. During high sea levels, carbonate production is more or less equally distributed between the neritic and pelagic realm, leading to lower carbonate content in basinal deposits. The genesis of deep-water carbonates during the Paleozoic is somewhat enigmatic, because calcareous plankton only evolved in

Carbonate Environments, Figure 26 (a) Outcrop of Cretaceous chalk in Etretat, northern France. Dark spots are silicified *Thalassinoides* burrows. the Mesozoic. Potential Paleozoic contributors include cephalopods, ostracods, tentaculites, calcispheres, and possibly very fine-grained detritus from the neritic realm. Cephalopod limestone is a typical Paleozoic deposit of shallow basins or deeper submarine rises with no modern counterpart (Wendt and Aigner, 1985).

Summary

Carbonate depositional environments were described in an idealized cross section from terrestrial to transitional, shallow marine, and to deep marine realms. Environments discussed include springs, lakes, subaerial exposure horizons, beaches and shores, tidal flats, restricted, open-rimmed, isolated shelves and platforms, ramps, tropical and cold deep-water reefs and mounds, slopes, and deep sea basins. The great majority of carbonates forms in the

marine realm, and, carbonate formation is largely a product of biological activity. Biological control is either direct, e.g., during growth of shells and skeletons of invertebrates such as corals, mollusks, brachiopods, echinoderms, and sponges, tests of foraminifera or carbonate particles produced by calcareous algae or coccolithophorids. Indirect biological control relates to metabolic processes, e.g., photosynthesis of microbes, which triggers carbonate precipitation. Abiotic formation of carbonates is the exception and includes the formation of some carbonate muds, cements, certain dolomites, and non-skeletal grains such as grapestones, lumps, or ooids. Elevated temperature and salinity, high concentrations of calcium, magnesium, and carbonate ions, low pressure, and CO₂-removal are major environmental parameters that potentially trigger abiotic carbonate formation.

Carbonate minerals

Definition

Carbonates. The term carbonates comprises solid phases such as minerals and amorphous substances, which basically consist of cations and triangular carbonate groups.

Introduction

The most common carbonate minerals in natural surroundings are calcite (CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$). These minerals comprise about 90 wt.% of carbonates within the Earth's crust and 10–15 wt.% of sedimentary rocks. The proportion of dolomite to calcite increases with decreasing geological age, representing the potential for transformation of calcium carbonate to dolomite at elevated temperature and high molar Mg^{2+} to Ca^{2+} ratio during geological history. Additional carbonate

minerals are numerous, but occur in rather special natural surroundings.

The occurrence and formation of carbonate minerals is mostly related to the precipitation from aqueous solutions and to a lesser extent to the crystallization from carbonate melts. In aquatic systems carbonate formation may be inorganically or biogenically induced (e.g., Morse and Mackenzie, 1990; Dove et al., 2003; Morse et al., 2007). Inorganic precipitation occurs from supersaturated solutions to form evaporites in marine and terrestrial environments, ooids in shallow water, saline lake deposits, speleothems in caves, sinter from spring water, hydrothermal ores, etc. Biogenic precipitation is mostly related to carbonates as skeletal parts and in tissues of marine and non-marine organisms such as foraminifera, coccoliths, corals, bivalves, and prokaryotes. The main mass proportion of carbonates is built from biogenic activity, whereas less arises from inorganic origin.

Once carbonate particles are formed, sedimentation may yield shelf deposits of carbonate sand or mud, deep sea ooze, or mud in lakes. Compaction, cementation, and diagenetic reactions result in lithification to limestone or calcareous marl and sandstone. Under elevated temperatures and pressures, the primary limestone may be transformed to, for example, dolomite rocks or marble.

Crystal structure and chemical composition

The basic units of carbonate minerals are cations and the triangular carbonate groups (CO_3^{2-}). The crystal structure of carbonate minerals is strongly related to the ionic radius of the cation versus the oxygen ion (e.g., Reeder, 1990). As the Ca:O ionic radius ratio in CaCO_3 is close to the upper limit for 6-coordination, CaCO_3 can occur in 6- and 9-coordination of Ca to O yielding calcite and aragonite, respectively. Accordingly, anhydrous carbonate minerals of smaller and larger cations compared to Ca^{2+} crystallize isostructurally to calcite and aragonite, respectively: (1) In the *calcite type* (trigonal carbonates), the carbonate group lies in planes at right angles to the threefold *c*-axis and the metal ions in alternate planes with a sixfold coordination of metal ions to oxygen ions (Figure 1). Metal ions of anhydrous carbonates of the *calcite type* are, e.g., Fe^{2+} , Mg^{2+} , Mn^{2+} , Cd^{2+} , and Zn^{2+} (small cations; see minerals in Table 1). (2) In the *aragonite type* (orthorhombic carbonates), a ninefold coordination of the cation to oxygen ions exists. Respective metal ions of anhydrous carbonates are, e.g., Ba^{2+} , Sr^{2+} , and Pb^{2+} as well as rare earth elements such as Sm, Eu, and Yb (large cations; Table 1).

Beside calcite and aragonite, the third CaCO_3 polymorph vaterite (hexagonal; see Figure 2) and amorphous calcium carbonate phases (ACC) can occur. Hydrus CaCO_3 minerals comprise amorphous $\text{CaCO}_3 \cdot \text{H}_2\text{O}$, monohydrocalciumcarbonate ($\text{CaCO}_3 \cdot \text{H}_2\text{O}$), and ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$). In analogy to calcium, a set of hydrus magnesium carbonates appears: Nesquehonite ($\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$), landsfordite ($\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$), and hydromagnesite ($\text{Mg}_5(\text{OH})_2(\text{CO}_3)_4 \cdot 4\text{H}_2\text{O}$).

Carbonates, Table 1 Densities and cation radii, and solubility products ($pK_S = -\log(K_S)$ at 25°C and 1 atm) of common carbonate minerals

Mineral	Formula	Density (g cm ⁻³)	Cation radius (pm)	pK_S
<i>Trigonal</i>				
Calcite	CaCO ₃	2.71	100	8.48
Siderite	FeCO ₃	3.80	78	11.03
Magnesite	MgCO ₃	2.96	72	8.10
Rhodocrosite	MnCO ₃	3.13	83	10.50
Otavite	CdCO ₃	4.26	95	12.10
Smithonite	ZnCO ₃	4.40	74	10.00
Dolomite	CaMg(CO ₃) ₂	2.87	-	17.09
Monohydrocalcite	CaCO ₃ ·H ₂ O	2.43	100	7.15
<i>Orthorhombic</i>				
Aragonite	CaCO ₃	2.93	118	8.34
Witherite	BaCO ₃	4.43	147	8.56
Strontianite	SrCO ₃	3.70	131	9.27
Cerussite	PbCO ₃	6.60	135	13.13
<i>Hexagonal</i>				
Vaterite	CaCO ₃	2.54	100	7.91
<i>Monoclinic</i>				
Ikaite	CaCO ₃ ·6H ₂ O	1.77	100	6.62
<i>Amorphous</i>				
Amorphous calcium carbonate (ACC)	CaCO ₃	-	100	6.40

Ordered double carbonate minerals are dolomite, ankerite (CaFe(CO₃)₂), kutnahorite (CaMn(CO₃)₂), huntite (Mg₃Ca(CO₃)₄), and shortite (Na₂Ca₂(CO₃)₃). In the structure of dolomite, distinct Mg²⁺ and Ca²⁺ layers alternate with CO₃²⁻ layers, whereas in the disordered protodolomite (MgCa(CO₃)₂) Mg²⁺ and Ca²⁺ are randomly distributed in the cation layer, as in Mg calcite. Carbonate minerals may contain hydroxide ions, like the copper carbonates malachite (Cu₂(OH)₂CO₃) and azurite (Cu₃(OH)₂(CO₃)₂), where the respective formation is sensitive to the CO₂ partial pressure. Typical alkali carbonate minerals are natron (Na₂CO₃·10H₂O), nahcolite

(NaHCO₃), trona (Na₃(CO₃)(HCO₃)·2H₂O), and kalicinite (KHCO₃).

Solubility and stability

The solubility of carbonate minerals is expressed by the solubility product, $K_S = (Me^{2+}) \cdot (CO_3^{2-})$ for divalent cations. Parentheses denote the activities of aqueous species at thermodynamic equilibrium. In aqueous environments the stability of minerals to each other is given by the individual values of the solubility product. At standard condition, aragonite and vaterite are more soluble than calcite (lowest K_S -value for calcite in Table 1). Accordingly, calcite is the thermodynamically stable CaCO₃ polymorph. At higher pressure, the more dense phase aragonite is the stable polymorph, although aragonite has a larger cation site due to 9-coordination of Ca to O.

Elevated temperatures cause a decrease of carbonate mineral solubility. Most reliable values of solubility products as a function of temperature are obtained by the empirical equation as compiled by Nordstrom et al. (1990). High pressure favors the dissolution of carbonate minerals as observed in seawater below ≈ 3 –5 km depths, the so-called carbonate compensation depth (CCD, e.g., Morse and Mackenzie, 1990). Deep-sea sediments below the CCD are free of calcite and aragonite.

At elevated pH in alkaline solutions, precipitation of carbonate minerals may occur due to high [CO₃²⁻] to [DIC] ratios ([]: molar concentration, DIC: dissolved inorganic carbon). Components of DIC comprise CO_{2(aq)}, H₂CO₃, HCO₃⁻, and CO₃²⁻, where CO_{2(aq)} is dominant over H₂CO₃ by a factor of 1,000 (see Usdowski, 1982). In acidic solutions the dissolution of carbonates is favored by a high H₂CO₃* content ([H₂CO₃*] = [CO_{2(aq)}] + [H₂CO₃]) and low [CO₃²⁻] to [DIC] ratios.

High ionic solute content generally results in high-dissolution capacities due to a decrease of ion activities versus the concentrations of total dissolved ions. Accordingly, calcite is more soluble in seawater than in freshwater. Seawater is slightly supersaturated with respect to calcite. Supersaturation means that the present ion activity product of the calcium and carbonate ion, $IAP = (Ca^{2+}) \cdot (CO_3^{2-})$, exceeds the K_S value for calcite (saturation degree: $\Omega = IAP/K_S > 1$), and precipitation of calcite may occur. In terrestrial solutions, like drip water in caves and spring water in karst areas, supersaturation with respect to carbonate minerals and sinter formation are mostly related to the degassing of CO₂, which results in an increase of pH.

Precipitation and dissolution

Several carbonate minerals such as calcite, witherite, and strontianite can be easily precipitated from aqueous solutions, whereas others, such as dolomite, are not easily precipitated. In the classical experimental study by Plummer et al. (1978), expressions for the dissolution and precipitation kinetics of calcite are given. Since the Plummer et al. study, various approaches have been used to model the

Carbonates, Figure 2 SEM images of inorganically induced CaCO_3 precipitates with typical shapes. (a) Rhombohedral calcite crystals associated with hexagonal plates of vaterite (CaCl_2 solution without magnesium; 30°C ; pH 9.0). (b) Small aragonite needles (CaCl_2 solution at a molar Mg^{2+} to Ca^{2+} ratio of 2; 20°C ; pH 9.0).

general relationships. Calcite dissolution kinetics is described by empirical rate expressions depending on the reaction rate constant, the reactive surface area, the volume of the solution, and the supersaturation state. More recently, Arakaki and Mucci (1995) interpreted the dissolution of calcite based on the surface complexation theory.

In natural environments, the observed precipitation and dissolution rates (R in $\text{mol m}^{-2} \text{s}^{-1}$) often disagree with the rates estimated from experimental approaches. This may be caused by an incorrect estimation of the reactive mineral surface. Lower rates in natural surroundings may also be due to inhibition by foreign ions or organic matter (e.g., Zaihua et al., 1995).

Gutjahr et al. (1996) showed that in addition to anions like phosphate, the occurrence of divalent ions such as Mg^{2+} , Fe^{2+} , Sr^{2+} , and Ba^{2+} significantly decreases the precipitation rates of calcite. In seawater, the transformation into the more stable phases is hindered by the high Mg^{2+} content. Thus, aragonite and high-Mg calcite are often found in marine sediments, although they are metastable against calcite and low-Mg calcite, respectively (Berner, 1966).

A main aspect of inhibition of carbonate precipitation in natural environments (e.g., biomineralization) and applied systems (e.g., scale formation) is the presence of dissolved organic matter, such as organic acids (e.g., Mann, 2001). For instance, polyaspartic acid can systematically and significantly modify the morphology and growth kinetics of calcite.

Isomorphic substitution

In natural systems, carbonate minerals are generally not pure substances. Impurities can be caused by isomorphic substitution of a host ion by foreign ions in a given crystal lattice. Isomorphic substitution of divalent cations in carbonate minerals depends on the cation radius, which accounts for the crystal structure and the solubility of carbonate minerals. Isomorphic substitution may result

in solid solution formation, as in the irregular but unsymmetrical SrCO_3 – CaCO_3 (aragonite type) solid solution.

Mechanisms of co-precipitation of foreign elements into carbonate minerals are complex and equilibrium thermodynamics may not be appropriate for dealing with many low-temperature reactions. On the other hand, trace element substitution in carbonate minerals can provide information about the environment conditions during formation.

The literature dealing with incorporation of trace elements into carbonate minerals is voluminous, especially with respect to the most abundant calcium and magnesium carbonates. As both the anhydrous magnesium and calcium carbonate crystallize in the *calcite type*, natural skeletal calcite can include up to about 25 mol% MgCO_3 to form so-called Mg calcite, which is isostructural with calcite. Low- and high-Mg calcites are defined by a limit of 4 mol% MgCO_3 with high-Mg calcite being less stable than low-Mg calcite. Only traces of magnesium are incorporated into aragonite as the cation sites are larger due to 9-coordination of Ca to O. Consequently, the larger Sr^{2+} ion is readily incorporated into aragonite, and less Sr^{2+} substitution occurs in calcite.

In the case of a solid CaCO_3 phase, a foreign element is incorporated into the crystal according to the overall expression

The related distribution coefficient is defined by the mole fractions X_{MeCO_3} and X_{CaCO_3} in the solid CaCO_3 and the molar Me^{2+} to Ca^{2+} ratio of the aqueous solution according to $D_{\text{Me}} = (X_{\text{MeCO}_3}/X_{\text{CaCO}_3})/([\text{Me}^{2+}]/[\text{Ca}^{2+}])$. The values of the experimental distribution coefficients for trace elements in carbonate minerals show a systematic behavior, but one that is different from that proposed by a thermodynamic equilibrium approach (e.g., Rimstidt et al., 1998; Lea, 2004; Boettcher and Dietzel, 2010).

The distribution coefficient of Mg^{2+} between calcite and aqueous solution is less than unity ($D_{\text{Mg}} \approx 0.02$ at 25°C). The higher the temperature, the more Mg^{2+} is incorporated into the calcite lattice (e.g., Oomori et al., 1987). In contrast, the distribution coefficients of Sr^{2+} in aragonite is larger than unity, and an increase in temperature results in less incorporation of Sr^{2+} into aragonite (Dietzel et al., 2004). Tesoriero and Pankow (1996) clearly showed that the incorporation of divalent cations into inorganically precipitated calcite is a function of precipitation rate. At low rates, a constant value of the distribution coefficient is reached representing thermodynamic equilibrium. Besides temperature and precipitation rates, the apparent D_{Me} values depend also on the concentrations of additional foreign ions via competitive substitution, the ionic strength of the solution, and the differential partitioning of the foreign cation on nonequivalent crystallographic faces of the carbonate mineral.

Trace element incorporation into carbonate minerals is widely used to estimate conditions of formation. For instance, Mg^{2+} to Ca^{2+} and Sr^{2+} to Ca^{2+} ratios in calcium carbonate minerals of foraminifera, coccoliths, bivalves, or in speleothems are used to estimate paleotemperature and environmental records as well as diagenetic alterations (e.g., Purton et al., 1999; Huang and Fairchild, 2001). The interpretation of datasets for trace element distribution in carbonate minerals is related to saturation states, precipitation rates, temperatures, and metabolisms of the organisms. Accordingly, recent studies of Elderfield et al. (2006) show a carbonate ion saturation state effect on Mg^{2+} incorporation in benthic foraminifera, and Freitas et al. (2006) show that Sr^{2+} to Ca^{2+} ratios in carbonate shell might be controlled by kinetic effects, the latter driven by seasonal variation in shell growth rate that is in turn influenced in part by seawater temperature.

Isotope geochemistry

Stable isotopes of carbon and oxygen of CO_3^{2-} molecules as well as cation isotopes in carbonate minerals are frequently considered in environmental studies to decipher the origin of components, conditions during formation, alteration effects, etc. (e.g., Ripperdan, 2001). For instance, stable oxygen isotopic fractionation between calcite and water has been widely used as a proxy for temperature and environmental changes in paleoceanography, speleology, and applied mineralogy (e.g., Dietzel, 2000; Spötl and Matthey, 2006). The basic concept is referred to the temperature sensitive oxygen isotope fractionation factor between calcite and water, $\alpha_{\text{calcite-water}} = (\delta^{18}\text{O}_{\text{calcite}} + 1,000) / (\delta^{18}\text{O}_{\text{water}} + 1,000)$. For example, Kim and O'Neil (1997) and more recently Coplen (2007) adopted from inorganic precipitation experiments and field studies the $\alpha_{\text{calcite-water}}$ values for equilibrium fractionation. From laboratory experiments and field studies it is widely accepted that the use of $\delta^{18}\text{O}$ as a temperature proxy is complicated by nonequilibrium fractionation (e.g., Kim and O'Neil,

1997; Mickler et al., 2004; Dietzel et al., 2009). In natural biogenic carbonates, the effect of growth rate on $\delta^{18}\text{O}$ values of carbonates is noticeable, with a rapid growth rate resulting in a lower $\delta^{18}\text{O}$ value (e.g., Adkins et al., 2003). Numerous temperature functions are used to estimate $\alpha_{\text{MeCO}_3\text{-water}}$ values for the respective cation content, crystal structure, and organism (e.g., Lea, 2004).

In the case of nontraditional stable isotopes, Mg and Ca isotopic distributions between aqueous cations and carbonate minerals are promising proxies to reconstruct environmental conditions during carbonate formation and to provide insight into geochemical cycles (e.g., Young and Galy, 2004; Tang et al., 2008, respectively). For example, ^{44}Ca is discriminated versus ^{40}Ca during calcium carbonate crystallization. Various models exist for the calcium isotope fractionation during precipitation of calcium carbonate from aqueous solution (e.g., Fantle and DePaolo, 2007). Although, effects of temperature, precipitation rate, crystal structure, and metabolism are identified as main factors for calcium isotope fractionation, future research is required to decipher individual fraction mechanisms.

Biom mineralization

Biom mineralization refers to the process by which living organisms form minerals. The most abundant carbonate biom minerals with respect to quantities and widespread distribution are calcium carbonates such as calcite and Mg calcite, and to a lesser extent aragonite, monohydrocalcite, and ACC (e.g., Weiner and Dove, 2003). Biom mineral phases often have shape, size, crystallinity, isotopic and trace signatures quite unlike their isotopic inorganically formed counterparts as a result of the interaction between organic macromolecules and an amorphous-crystalline phase transformation during early stages of biom mineralization. Sorting out the physiological effects from environmental signals provides a challenge for further scientific research.

Although, ACC is thermodynamically metastable it can be introduced as an important precursor of biom mineralization. Biom mineralization mechanisms and strategies for the biomimetic preparation of functional materials can be followed by transformation of ACC into crystallized calcium carbonates regulated by additives, e.g., functional polymer, proteins, and inorganic ions (Xu et al., 2008).

Han and Aizenberg (2008) showed that the ACC phase can be doped with foreign ions (e.g., Mg^{2+}) and organic molecules (e.g., dyes) and that these compounds later function as growth modifiers of calcite crystals. Such foreign components are incorporated into the crystals during the transformation process of ACC to calcite, which may indicate a vital effect on biogenically induced calcite. Lam et al. (2007) synthesized ACC in the presence of Mg^{2+} and polyaspartic acid. While the first Mg rich ACC precipitates showed short-range structures most similar to aragonite, the initial polyaspartic ACC precipitates possessed short-range structures resembling vaterite. The

influence of these additives on the crystallization of calcium carbonate is apparent even in the precipitation of the first amorphous precursor phase.

Summary

Carbonate minerals have a high diversity and are widely distributed throughout the Earth's crust. The most abundant carbonates contain calcium and magnesium such as calcite, dolomite, Mg calcite, and aragonite. For biogenically formed carbonates, precursor phases such as ACC are of special interest. In aqueous systems the stability of carbonates is related to the solubility product and the kinetics of dissolution and precipitation. Incorporation of foreign cations and isotopes into carbonates is mostly controlled by the composition of the solution, temperature, and precipitation rate. Thus, the chemical and isotopic composition of carbonates can be used as promising proxies to decipher environmental conditions during mineral formation and alteration. Lab experiments will be essential to provide insight about environmental changes throughout the geologic history from field data.

Montanuniversität Leoben, Leoben, Austria

Definition

Cathodoluminescence (CL) is the emission of visible light (also ultraviolet [UV] and infrared) of a solid material that is irradiated by an electron beam (in vacuum). During irradiation CL often changes. Besides CL, the emission of element-specific X-rays and backscattered, secondary and Auger electrons is caused (e.g., Walker and Burley, 1991). Moreover, the sample is heated by the electron beam, which represents an important cause for the alteration of CL characteristics during electron bombardment. Cathodoluminescence microscopy (CLM) combines CL with optical microscopy (in geosciences, generally polarizing microscopy). CL microscopic studies are mostly carried out on thin sections (uncovered, preferably polished), sometimes on up to one cm-thick samples, the latter preferably with polished surface as well. Depending on the instrument used (see below), samples can be studied uncoated or with a coating to avoid charging by the electron beam.

Two types of CL are known: intrinsic and extrinsic (for details see discussion by Remond et al., 2000). Intrinsic CL is purely due to lattice features, generally very weak and only visible if there are no activators present in adequate amounts. Extrinsic CL, the generally observable case, is caused by activators, which occur as trace elements. The activators may be supported by sensitizers that transmit energy to the activators. Quenchers are elements that reduce or even inhibit CL. The significance of sensitizers and quenchers is still in discussion. An important example is iron, which is generally considered as a quencher in carbonate minerals, and lead, which seems to be a sensitizer (e.g., Machel, 2000). In contrast to the view of iron as a quencher, Cazenave et al. (2003) showed in a recent study of doped calcite that Mn-activated CL in calcite can be uninfluenced by iron in a relatively wide range of iron concentrations. The question whether Pb and Zn can be sensitizers in calcite was discussed by Budd et al. (2000), who could not find any evidence for sensitizing by these trace elements.

In geosciences, CLM is a powerful tool for detailed analyses of rocks and minerals, including biogenic mineral substances (for a summary of CL data and earlier literature, see for instance Marshall, 1988, Remond et al., 1992 and Pagel et al., 2000). Intensity and wavelengths (colors) of emitted light may vary strongly for the same mineral phase or even within the same mineral grain, depending on genetically determined features. This is especially significant when a mineral substance is growing or recrystallizing under changing ambient conditions, often causing changes of CL intensity or color, sometimes revealing patterns of complex zoning. In most cases, such effects are not visible by optical microscopy. Therefore, for studies of biogenic mineral substances, CLM can

provide important information. In geosciences, CLM has been used for more than 40 years, resulting in a huge number of publications (for an outline of history, see for instance Pagel et al., 2000). In biology, probably the first CL study was performed by means of an electron microprobe by Cavallier (1975).

Instrumentation

CL studies can be carried out by (1) CLM with cold cathode equipment, (2) CLM with hot cathode equipment, and (3) scanning electron microscopy (SEM) and electron probe micro-analysis (EPMA), if the latter are equipped with CL detector or with an instrumentation for light optical observation/recording. For CLM, CL images can be recorded by conventional camera technique using film, video technique, or digital camera. However, today, digital camera and video techniques have generally replaced film techniques. For detailed and reproducible recording of CL colors, which is important for the determination of activators, optical spectrometers are applied (e.g., Gillhaus et al., 2001). Moreover, CLM can be combined with energy-dispersive X-ray spectroscopy (EDS), providing rapid elemental analysis (see below).

An overview for the application of SEM and EPMA for CL studies is given by Remond et al. (2000). These instruments allow the combination of CL with electron images and elemental analysis by means of EDS or wavelength-dispersive X-ray spectroscopy. Due to the influence of the chemistry of analyzed materials on backscattered electrons (BSE), corresponding electron images are especially interesting in combination with CL. Moreover, SEM offers the advantage of high spatial resolution, including spectrometric recording of CL colors. Monochromatic CL mapping by SEM, with the same resolution as for element mapping by means of EDS, was recently described by Edwards et al. (2007).

For cold cathode CLM, a vacuum chamber with fixed electron gun and x - y stage for sample movement is attached to the stage of a microscope. As the electron beam is directed from above, i.e., from the same side as the objective of the microscope, besides thin sections, up to one cm-thick samples can be studied as well. Care has to be taken with cold cathode CLM systems, to avoid too high energy flux, which can damage thin sections and increase the changes of CL intensity and colors during electron bombardment. Due to low vacuum, residual gas is ionized, preventing electron charging of the sample surface. Therefore, coating is not necessary. A disadvantage of cold cathode CLM systems, often mentioned in the literature (e.g., Walker and Burley, 1991), is that objects with very low CL intensity are not observable, or at least require too long exposure times for conventional camera film techniques. Witkowski et al. (2000), for instance, published excellent CL images of objects with low CL intensity, showing that former problems can be overcome by using a high-sensitivity digital video camera linked to a computer.

Besides optical spectroscopy, EDS is also possible with cold cathode CLM systems (e.g., Vortisch et al., 2003). Cold cathode CLM systems equipped with EDS can also be used for the analysis of opaque and nonluminescent materials as well as finely ground pressed powders (Vortisch, 2004). Cold cathode CLM systems are less expensive and easy to operate. Instrumental working conditions, vacuum, high tension and beam current are now automatically stabilized. The CL images used in this chapter were obtained by means of a cold cathode CLM system.

Hot cathode CLM systems operate at high vacuum, comparable to SEM. To prevent charging during electron bombardment, coating is recommended. Microscope, vacuum chamber with hot cathode, and x - y stage for sample movement are integrated. In contrast to cold cathode CLM systems, the sample may be less heated. Hot cathode CLM systems are generally regarded as being more suitable for objects with low CL intensity. Therefore, many publications including optical spectroscopy for the analysis of CL-activating trace elements are based on hot cathode CLM (e.g., Gillhaus et al., 2001; for interesting examples concerning geobiology, see e.g., Barbin, 2000; see below).

The irradiation of the sample is normally from below, opposite to the objective of the microscope, therefore only transparent objects (i.e., thin sections) can be studied.

CL in geobiology

CLM proved to be of special interest in the following areas of geobiology:

- Biogenic minerals in shells, bones, and other mineralized parts of organisms; structures and conditions of growth
- Processes of fossilization and transformation of biogenic mineral matter during diagenesis; mineralization of organic matter
- Microbial mineralization processes

Structures and growth conditions of biogenic minerals often reveal more details when CLM is applied. Barbin et al. (1991a), for instance, were able to distinguish winter growth rings from other parts of the shell of *Pecten maximus* by means of CL, observing an inverse relation between growth velocity and CL intensity. In a recent study of experimental biology, Barbin et al. (2008) were testing the uptake of manganese of the oyster species *Crassostrea gigas* (Mn^{2+} was added as $MnCl_2$ to a tank with seawater where the oysters were living). By means of CLM and microchemical analysis, the authors could prove the daily incorporation of Mn to the growing shell. Mn was incorporated simultaneously to calcitic and aragonitic parts of the shell. CL colors were yellowish for calcite and greenish for aragonite. A comparable differentiation in CL color between calcite and aragonite was observed in the shell of *Halotis* by Hawkes et al. (1996) during

Cathodoluminescence Microscopy, Figure 1 Thin section of Lower Ordovician limestone from Möckleby (southern Öland, Sweden), revealing various stages of diagenetic alteration of carbonate fossils (interpretation Maurits Lindström); optical ((a), plane polarized light) and cathodoluminescence (CL) images (b); height of images: 1.6 mm. 1. Trilobite fragment, completely recrystallized but still clearly separable from surrounding sediment by CL. 2. Recrystallized echinoderm fragment with uniform extinction under crossed polarizers, showing changing chemical conditions during recrystallization. The innermost part with dull CL indicates an (almost) unchanged chemical composition. 3. Brachiopod fragment, consisting of fibrous calcite with sediment matrix entering between the fibers and (later) diagenetically recrystallizing. A larger inner part of this fragment shows very low CL intensity, indicating recrystallization without considerable alteration of the original chemical composition. 4. Series of cement generations filling a small cavity (probably after diagenetically dissolved, siliceous sponge needle), demonstrating the chemically complex early diagenetic history of this limestone layer that was already lithified near the interface sediment/seawater.

Cathodoluminescence Microscopy, Figure 2 Thin section of Upper Cretaceous glauconitic sandstone, showing intergrowth of glauconite (no CL) and calcium phosphate (CaP, pink CL); optical ((a), plane polarized light) and CL images (b); height of images: 2 mm. The intergrowth with CaP (determined by scanning electron microscopy–energy-dispersive X-ray spectroscopy (SEM–EDS)) indicates glauconitization of organic substances, especially fecal pellets (Schinagl and Vortisch, in prep.). 1. Glauconite with an outer rim of CaP. 2, 3. Compared with grain 1, less intensive glauconitization of organic material, indicated by considerable proportions of CaP inside the grains. 4, 5. Grains consisting predominantly of CaP, with minor proportions of glauconite. 6, 7. Glauconite grains with small inclusions of carbonate minerals. *Bright yellow CL*: carbonate (probably dolomite); *bright blue CL*: potassium feldspar; *brownish to violet CL*: quartz.

a similar experimental study. CL colors observed by these authors were orange-red for calcite and yellow-green for aragonite.

Biogenic minerals are generally transformed during diagenesis by processes such as recrystallization or replacement. By means of CLM, it is often possible to observe primary structural details even after diagenetic alteration of the biogenic material. Baumgartner-Mora and Baumgartner (1994) have shown good examples for Miocene foraminifera from Costa Rica. When biogenic minerals are investigated with regard to primary stable isotope geochemistry, it is important to know whether the geochemistry of the analyzed material has been changed or not. By means of CLM, Wierzbowski and Joachimski (2007) selected carbonate shells (calcitic and aragonitic), which were nonluminescent or showed only intrinsic bluish CL, for oxygen and carbon isotope analysis, with the argument that diagenetic alteration of carbonate minerals generally results in the enhancement of CL intensity. Barbin et al. (1991b) already recommended the usage of only nonluminescent biogenic carbonate for the investigation of past sea water composition. These authors emphasize that even recent carbonate shells may show

CL of considerable intensity. Figure 1 shows examples for different steps of diagenetic recrystallization of fossils in a Lower Ordovician limestone from Sweden.

The postdepositional mineralization of organic materials may also represent interesting objects for CLM. Götze and Rößler (2000) studied silicified Permian wood. On the base of CL, they concluded that a polyphase process of silicification included an initial hydrothermal phase. Among other analytical procedures, CLM was also applied by Scott and Collinson (2003) for the analysis of Tertiary and Jurassic permineralized woods that contain calcite and Ca phosphate as important mineral phases. Coprolites of Upper Triassic carnivore vertebrates were investigated by Hollocher et al. (2005), who suggest an early onset of mineralization, starting with the formation of apatite. Further minerals are calcite and glauconite. An example for the association of glauconite and apatite, probably due to the mineralization of fecal pellets, is shown in Figure 2.

Reitner et al. (2005, 2006) applied CLM, among other methods, for the study of microbial mineralization processes in methane-derived carbonate buildups in the Black Sea sediments. An example of this work is given in

Cathodoluminescence Microscopy, Figure 3 Thin section of methane-derived carbonates from the Black Sea (Reitner et al., 2005, 2006). Comparison of light, ultraviolet (UV), and CL microscopy with element distribution of Mg, Sr, and Mn. Length of individual image 40 mm. (Light optical image and CL image compiled of about 200 images, UV image of about 600 single images.) The carbonates were precipitated within thick microbial mats, mainly constructed of anaerobic methane-oxidizing microbial communities. The microbial mats are differentiated in an outer black zone, characterized by the so-called ANME 2 (ANAerobic METHanotrophs) microbial community, and an inner orange/pink zone characterized by the so-called ANME 1 microbial community. ANME 2 community precipitates high Mg–calcite (HMGC), which is rich in Mn. The incorporation of Mn within the calcite crystal lattice causes a strong CL of the HMGC. ANME 1 community precipitates a Sr-rich nonluminescent aragonite.

Figure 3. Microbial mats with their methane–sulfate redox systems are the place where strongly luminescent high Mg–calcite is formed as a first carbonate phase. This first carbonate phase interfingers with nonluminescent aragonite, with the latter finally creating the thrombolitic fabric of the towers (Reitner et al., 2005). Another example for the significance of microbial activity at the methane–sulfate interface for early mineralization of marine sediments, also studied by means of CLM, was described by Meister et al. (2007). This work reports on early, near-surface dolomite cementation in Quaternary sediments from the Peru continental margin.

Conclusions

CLM is successfully applied in all areas of geobiology where mineral substances are involved. Important examples are biogenic minerals in shells, bones, and other mineralized parts of organisms; their structures and conditions of growth and processes of fossilization; mineralization of organic matter; microbially influenced processes of mineralization and formation of sedimentary structures. Minerals often studied by CLM are carbonates, phosphates, and silica minerals.

Acknowledgments

I am grateful to late Prof. Dr. Maurits Lindström for the interpretation of the Lower Ordovician sample (Figure 1), to Prof. Dr. Joachim Reitner for providing Figure 3 (including figure caption), to Jay Morgan for important discussions and language corrections in the manuscript, and to Dr. Reinhard Gratzner for his help with graphical work.

CHEMOLITHOTROPHY

Volker Thiel
 University of Göttingen, Göttingen, Germany

The term “Chemolithotrophy” refers to the gain of energy for cell biosynthesis and maintenance from the oxidation of inorganic compounds (= electron donors), in the absence of light (Kelly and Wood, 2006). The process was first described by the Russian microbiologist Sergej Winogradsky (1887, 1888).

Chemolithotrophy is a strategy unique to some prokaryotes (i.e., Bacteria and Archaea), the so-called chemolithotrophs. Whereas there is no known macrofauna possessing the capability of chemolithotrophy, some animals such as particular tubeworms and bivalves can form symbioses with chemolithotrophs, (e.g., at cold seeps or in hydrothermal environments). There exist many inorganic electron donors that can fuel chemolithotrophs involving geologic, biologic, and anthropogenic sources. Reduced sulfur, nitrogen and iron species and hydrogen are the most common substrates (Table 1). If chemolithotrophs are able to use

Chemolithotrophy, Table 1 Some common reactions performed by chemolithotrophs

Electron donor	Reaction	Organism	$\Delta G_0'$ (kJ/reaction)
Hydrogen	$\text{H}_2 + \frac{1}{2} \text{O}_2 \rightarrow \text{H}_2\text{O}$	Hydrogen bacteria	–237.2
Sulfide	$\text{HS}^- + \text{H}^+ + \frac{1}{2} \text{O}_2 \rightarrow \text{S}^0 + \text{H}_2\text{O}$	Sulfur bacteria	–209.4
Sulfur	$\text{S}^0 + \frac{1}{2} \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 2\text{H}^+$	Sulfur bacteria	–587.1
Ammonium	$\text{NH}_4^+ + \frac{1}{2} \text{O}_2 \rightarrow \text{NO}_2^- + 2\text{H}^+ + \text{H}_2\text{O}$	Nitrifying bacteria	–274.7
Nitrite	$\text{NO}_2^- + \frac{1}{2} \text{O}_2 \rightarrow \text{NO}_3^-$	Nitrifying bacteria	–74.1
Iron	$\text{Fe}^{2+} + \text{H}^+ + \frac{1}{4} \text{O}_2 \rightarrow \text{Fe}^{3+} + \frac{1}{2} \text{H}_2\text{O}$	Iron oxidizing bacteria	–32.9

Source: Adapted from Madigan and Martinko (2006)

Chemolithotrophy, Figure 1 *Left:* Filamentous sulfur bacteria forming a bacterial mat in the Tunnel of Äspö, Sweden. These chemoautotrophs oxidize sulfide to elemental sulfur. Holes in the filaments are preparation artifacts that reflect the former location of intracellular sulfur granules. The filaments are approximately 1 μm in diameter (Scanning electron microscope image courtesy of J. Reitner). *Right:* Massive iron-oxidizing microbial mats developing at an underground spring discharging water rich in reduced iron (Fe^{2+}). The chemolithotrophic bacterium *Gallionella ferruginea* is a main component of the microbial community at this site (Tunnel of Äspö, Sweden) and is responsible for the production of large amounts of orange coloured iron oxides and hydroxides. The area displayed is about 1 m wide.

CO_2 as their carbon source (most are) they are referred to as chemolithoautotrophs. Well-known examples of chemolithotrophs relevant in geobiology are sulfur-oxidizing bacteria (e.g., *Beggiatoa*; *Thiomargarita*) and iron-oxidizing bacteria (see entries “*Fe(II)*-Oxidizing Prokaryotes,” “*Gallionella*”) (Figure 1).

CHERTS

Volker Thiel
 University of Göttingen, Göttingen, Germany

Chert is a sedimentary rock mainly consisting of micro- or cryptocrystalline (=submicroscopic) quartz (SiO_2) varieties.

Cherts often have an “indirect” biogenic origin as they result from re-precipitation of dissolved opal-A shells derived from microorganisms such as diatoms (diatomite, diatomaceous cherts, see also entry “*Diatoms*”) and radiolarians (radiolarite, see also entry “*Protozoa (Heterotroph, Eukaryotic)*”). Postsedimentary dissolution of these shells leads to the accumulation of silica-rich fluids within pore waters, thus, inducing precipitation of metastable cristobalite, also known as opal-CT (Konhauser, 2007). Opal-CT may, under increasing temperatures and pressures, be converted into stable quartz. Chert may also originate from microbial silification, and it may form, with or without microbial mediation, in hydrothermal environments (Konhauser et al., 2004; Jones et al., 2004, see also entries “*Sinter*” and “*Hot Springs and Geysers*”). Depending on the content of clay and other minerals, chert may grade into siliceous shales or -mudstones. The color of cherts may vary greatly with the content of accessory elements. Iron (hematite), for instance, gives rise to red varieties called “jasper.” Banded cherts, with often colorful, rhythmic layers, are called “agate.”

Chert may occur as extensive layers (bedded cherts) within sedimentary formations as well as in concretionary

nodules. For example, vast deposits of bedded cherts, alternating with iron minerals, are found within the Precambrian “Banded Iron Formations” (see entry). “Flintstones” on the other hand, are dark-colored chert nodules that precipitated in chalk such as in the Upper Cretaceous Maastrichtian Formation in Middle Europe. Here, the SiO₂ mainly derived from diagenetically dissolved, and re-precipitated, sponge spicules. Deposits with a high content of sponge-derived SiO₂ dispersed in sedimentary rocks are called “spiculites.”

Cherts may provide an excellent matrix for the long-term preservation of macro- and microfossils as well as chemical and isotopic signatures, due to their density and resistance. Examples are the Rhynie Chert that uniquely preserved an early Devonian community of plants, animals, bacteria, and fungi (Taylor et al., 2009), and numerous Precambrian cherts that provide an exciting view on the early dawn of life on Earth (Derenne et al., 2008; Westall et al., 2006, see entry “*Biosignatures in Rocks*”).

CHONDRITES

Chondrites are the most common class of stony meteorites. Chondrites largely consist of iron- and magnesium silicate minerals and remain unaffected from melting and differentiation. Therefore, chondrites are considered to reflect the elemental composition of the original solar nebula. *Carbonaceous chondrites* are a rare variety of chondrites containing numerous organic compounds, including amino acids. See “*Meteoritics*” for further reading.

CHROOCOCCIDIOPSIS

Burkhard Büdel

University of Kaiserslautern, Kaiserslautern, Germany

The unicellular cyanobacterial genus *Chroococcidiopsis* was first described by Geitler (1933) from Sumatra, where it was found in warm springs.

Definition

The cyanobacterial genus *Chroococcidiopsis* is defined as having more or less spherical cells surrounded by a thin, firm, colorless, sometimes layered extra-cellular polysaccharide sheath (EPS). The cell has an S-layer of a special ribbon-like type, not found in other cyanobacteria so far (Büdel and Rhiel, 1985). It often occurs in large agglomerations of spherical or irregular shape. Fully grown cells (usually 2–6 µm in diameter) divide in two modes: (1) after one or two binary divisions with planes rectangular to each other, resulting daughter cells continue to divide in different planes without intermediate growth (successive multiple divisions); (2) by successive or almost spontaneous irregular cell division (multiple fission) without intermediate growth. In both types, the final daughter cells are very small (1–3 µm in diameter) and are released by rupture of the sheath envelope.

Presently, the genus *Chroococcidiopsis* comprises 14 different species (Komárek and Anagnostidis, 1998). *Chroococcidiopsis* is closely related to the heterocyst-containing, filamentous cyanobacteria (Nostocales, Stigonematales, see entry “*Cyanobacteria*”) and forms their natural sister group (Fewer et al., 2002). The current species concept needs revision.

In terms of ecology, *Chroococcidiopsis* is most interesting because of the wide variety of habitats it colonizes. Among these are different extreme biotopes such as thermal or mineral springs (see entry “*Hydrothermal Environments, Terrestrial*”), and extremely hot and cold deserts (Antarctica), where it is epilithic or endolithic on rocks (Figure 1a–h; see entry “*Endoliths*”). The genus is a common photobiont of the cyanolichens of the

Chroococcidiopsis, Figure 1 *Chroococcidiopsis* endolithic in rocks. (a) Sandstone of the Clarens formation, Golden Gate Highlands National Park, South Africa. CLAY AUTHIGENESIS, BACTERIAL

Kurt O. Konhauser
 University of Alberta, Edmonton, Alberta, Canada

Definition

The formation of clay minerals in situ through the direct or indirect action of bacteria.

Overview

Clays are one of the largest and most diverse assemblage of minerals known. The vast majority of clay minerals are aluminum silicate in composition, with various other cations substituted into the crystal lattice. The replacement of either Si or Al can lead to an excess of negative charge, which is either neutralized by the adsorption of additional cations onto the outer mineral surfaces or within the interlayer spaces.

Within the past 2 decades, field studies have led to the general recognition that bacteria can mediate the formation of clay minerals. Some clays form as replacement products from the alteration of primary minerals. In this regard, the bacterial community growing on the rock surface potentially function initially as the weathering agents (through the production of organic acids or ligands that facilitate mineral dissolution) and later as reactive surfaces for the nucleation of secondary clay phases. For instance, Konhauser et al. (2002) documented that highly altered rocks found within active steam vents at Kilauea Volcano, Hawaii, contained bacteria with small (<500 nm in diameter) grains of smectite $[(\text{Al}_{1.6}\text{Fe}_{0.4})(\text{Si}_{3.8}\text{Al}_{0.2})\text{O}_{10}(\text{OH})_2\cdot\text{K}_{0.2}]$ attached directly to the outer cell walls.

Many of the elements now incorporated into the clays originated when the volcanic glass dissolved and released them into the pore waters. Leveille et al. (2002) similarly documented the formation of kerolite $[\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2 \cdot n\text{H}_2\text{O}]$ in association with microbial mats colonizing the surfaces of walls and ceilings within basaltic sea caves on the north coast of Kauai, Hawaii. That microorganisms were in some way involved in mineral formation was suggested by the lack of kerolite within basalt vesicles near the rock surface or in the carbonate-rich evaporitic coatings found on other exposed surfaces without the presence of microbial mats.

Other clays form in environments far removed from the actual sites of weathering. The best examples come from biofilms retrieved from the sediment–water interface of lakes and rivers. Ferris et al. (1987) initially described complex (Fe,Al)-silicates on bacterial cells growing in metal-contaminated lake sediment in northern Ontario. These precipitates ranged from poorly ordered and uncharacterized phases to crystalline forms of the Fe-rich chlorite, chamosite $[(\text{Fe})_3(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_2]$. Since then, similar clayey precipitates have been reported from various rivers around the world (e.g., Konhauser et al., 1998). What is particularly remarkable about bacterially mediated clays is that they share a number of properties, irrespective of the chemical composition of the waters from which they were sampled: (1) They are generally amorphous to poorly ordered structures. (2) All have grains sized $<1\ \mu\text{m}$, although the majority are $<100\ \text{nm}$. (3) The grains have a composition dominated by iron, silicon, and aluminium in varying amounts.

Based on the observations from natural studies, a general sequence of events leading to clay biomineralization can be adduced (Konhauser and Urrutia, 1999). In the initial stages, a bacterium adsorbs any number of different free aqueous iron species, i.e., Fe^{2+} , Fe^{3+} , $\text{Fe}(\text{OH})^{2+}$, and $\text{Fe}(\text{OH})_2^+$, depending on solution chemistry and redox potential. Adsorption can occur on either the cell wall,

which is frequently lined with anionic carboxyl and phosphate functional groups, or to the more neutrally charged carbohydrate-rich extracellular layers that surround the cell, including sheaths and capsules – the latter are the organic components that make up the bulk of biofilms. If the soluble iron concentration around the cell surface exceeds the solubility product of ferric hydroxide, then the reaction between the bound iron with dissolved iron will lead to the development of small ($\sim 100\ \text{nm}$ in diameter), dense, mineral aggregates on the outer cell surface (Figure 1a). Indeed, it has been shown experimentally that a continuum exists between cationic iron sorption and precipitation reactions at bacterial surfaces; with the three stages of (1) sorption, (2) surface site saturation and (3) precipitation, all evident in Langmuir-type isotherms relating the solid-phase concentration of Fe(III) to the equilibrium proton and soluble Fe(III) concentrations (Warren and Ferris, 1998). Alternatively, bacteria can attract preformed nanometer-sized ferric hydroxide particles from suspension (Glasauer et al., 2001), thereby negating the need for the nucleation step. In most solutions, iron is only found in trace amounts compared to other ions, particularly silica. Under those conditions, the adsorbed/particulate iron may instead serve as kinetically favorable site for the development of more complex precipitates of variable clay composition, morphology, and structure (Figure 1b).

Why these clays form is likely as follows. In the pH range of most natural water bodies, negatively charged counter-ions, or those molecules that are neutrally charged but exhibit residual surface electronegativity (e.g., oligomeric and colloidal silica species), accumulate near the solution-adsorbed iron/solid interface to neutralize the net positive charge of iron. Two surface species of iron oxide exist in this pH range; FeOH_2^+ and $\text{Fe}(\text{OH})^0$, but the majority of the surface charge is positive at circumneutral pH. The initial (Fe,Al)-silicate phases then form via hydrogen bonding between the hydroxyl groups

Clay Authigenesis, Bacterial, Figure 1 Transmission electron micrographs (TEM) of bacteria (stained) from the Rio Solimões in Brazil. associated with the cell-bound iron and the hydroxyl groups in the dissolved silica, aluminum, or aluminosilicate complexes (e.g., Taylor et al., 1997; Davis et al., 2002). Exactly how these reactions occur in nature has not been ascertained, but we do know that dimeric silica (the species that accounts for more than 99% of the oligomeric silica in natural waters) is highly reactive toward iron hydroxide surfaces (Reaction 1), and that oligomeric silica exhibits a strong affinity for dissolved aluminum, forming soluble hydroxy-aluminosilicate ions (e.g., Reaction 2) that subsequently react with cell-bound iron.

This arrangement of ions forms an electric double layer with iron attaching to the bacterial surface as an inner sphere complex, while the silica-aluminosilicate species attach as more diffuse outer layers. The surface charge of these composites is inevitably dependent upon the solution pH, the ionic strength of the solution, and the time of reaction, such that as the particles age more silica (and aluminium) sorb. Interestingly, this mechanism of binding Fe to the bacterial cell surface and subsequent reaction with Si and Al from solution has been shown in experimental systems with *Bacillus subtilis* (e.g., Urrutia and Beveridge, 1994). Accordingly, if the microbial mats are subject to sufficiently concentrated solutions, then continued reaction of the dissolved components to the Fe-bearing solid interface eventually results in the formation of amorphous to poorly ordered clay phases. Often, these reactions lead to the partial and complete encrustation of some bacterial cells as abiological surface reactions accelerate the rate of mineral precipitation: in some biofilms, the density of clayey material surrounding individual cells can extend hundreds of nanometers away from the cell surface (Figure 2). Over time, these hydrous compounds dehydrate, some converting to more stable crystalline forms. This latter material presumably uses some fraction of the precursor surface as a template for its own growth, in effect circumventing the need for direct nucleation (Steeff and van Cappellen, 1990). Once it begins to grow, the more stable clay phase increases its own surface area until it can control the composition of the proximal solution. When this happens, the saturation state of the solution moves below the solubility of the precursor, inhibiting further growth, or even dissolving the precursor.

The reactions above are naturally an oversimplification because a number of inorganic processes are also at play. It is well known that soluble Al–Si complexes precipitate as poorly ordered Al–silicates when a state of supersaturation is achieved (Wada and Wada, 1980). Moreover, Fe ions can readily be incorporated into those structures

Clay Authigenesis, Bacterial, Figure 2 TEM image of highly encrusted bacterium from the Speed River in Ontario, with clay minerals extending over 500 nm away from cell surface. Arrow indicates surrounding capsule in which the clay minerals have formed. Scale bar = 500 nm.

leading to clay-like products (Farmer et al., 1991). All these reactions can conceivably take place in the proximity of bacterial surfaces or within the extensive EPS, particularly since diffusion through the polysaccharide matrix is inherently slow, and a microenvironment can be established that is conducive to mineralization. Additionally, colloidal species of (Fe, Al)-silicate composition that either form initially in the water column or are products of weathering and soil formation, may react directly with the outermost cellular layers. It follows that anything which will neutralize or diminish the charge of the colloids (e.g., bacterial surface if colloids are positively charged or adsorbed iron if the colloids are negatively charged) will cause the particles to flocculate out of solution.

One of the intriguing questions that arises from the observation of bacterial cells completely encrusted in clays is why do they allow for mineralization to occur? It has been established that bacteria have the ability to partially control their surface charge (Doyle, 1989). During metabolism, a membrane-induced proton motive force continuously pumps protons into the wall fabric that effectively compete with metal ions for anionic wall sites (Urrutia et al., 1992). Subsequently, living bacteria may be able to reduce authigenic mineral formation (and detrital mineral adhesion) on their cellular surfaces, unless environmental conditions exceed their capacity to compensate. In most aqueous environments with low dissolved solutes, this condition should not arise. Therefore, the presence of epicellular minerals on bacteria suggests that (1) the cells observed under the electron microscope had lysed prior to mineralization, or (2) that the mineralized matrix is in some way advantageous to the microorganism. Several possibilities for the latter

exist. First, clays provide a good source of exchangeable inorganic nutrients readily available to microbes (Tazaki et al., 1994). Second, clays such as montmorillonite stimulate the respiration of bacteria by maintaining the pH and water content of the environment at a level suitable for growth (Stotzky and Rem, 1966). Third, the formation of an external mineralized matrix may protect the living cells from the detrimental effects of toxin-producing microorganisms (Habte and Barrion, 1984) and predation by grazing protozoans (e.g., Heynen et al., 1988).

Summary

Microorganisms are commonly associated with fine-grained (Fe, Al)-silicates of variable composition. The inorganic phases develop in a predictable manner, beginning with the adsorption of cationic iron to anionic cellular surfaces, supersaturation of the proximal fluid with Fe (III), nucleation and precipitation of a precursor ferric hydroxide phase on the cell surface, followed by reaction with dissolved silica and aluminium, and eventually the growth of an amorphous clay-like phase.

COCCOLITHOPHORES

Volker Thiel

University of Göttingen, Göttingen, Germany

Coccolithophores (coccolithophorids) are a group of unicellular, marine, planktonic algae belonging to the haptophytes (Prymnesiophyta). The coccolithophores are capable of controlling the intracellular precipitation of calcite onto organic plates and the assembly of the mature carbonate scales at the cell surface. These scales, the coccoliths, are spherical or oval, often intricately patterned and generally less than 20 µm in diameter. Given the abundance of coccoliths in sediments, coccolithophorids have been playing a major role in the global carbon budget. They were very abundant in the Mesozoic era, particularly in the Cretaceous period, in which they became a major component of the “Chalk” lithology (e.g., White Cliffs of Dover, England). Today, coccolithophorids are accounting for about a third of the total marine CaCO_3 production, and coccoliths are a major component of the

modern deep-sea calcareous oozes. The most widespread modern species is *Emiliania huxleyi*. Recent studies showed that calcification and net primary production in *E. huxleyi* have increased by ~40% over the last 220 years due to ocean acidification in response to rising atmospheric CO₂ partial pressures (Iglesias-Rodriguez et al., 2008). Contributions of sedimentary organic matter from coccolithophorids, and other haptophyte algae, can be by tracked by particular lipid biomarkers, the long-chain alkenones. These compounds are often used as a “paleothermometer” for the estimation of past sea surface temperatures (see entry “*Biomarkers (Organic, Compound-Specific Isotopes)*”). For detailed reading and further references please see entry “*Algae (Eukaryotic)*.”

COLD SEEPS

Robert G. Jenkins
Yokohama National University, Yokohama City, Japan

Synonyms

Diffusive seep; Ground water seep; Hydrocarbon seep; Methane seep; Oil seep. The terms “seep” and “seepage” can be used as alternates

Definition

Fluid flow containing reduced compounds, e.g., methane or hydrogen sulfide (see entry *Sulfur Cycle*), with almost no temperature anomalies compared with ambient seawater gushing out from or reaching very close proximity to the seafloor.

Introduction

Active water circulation systems can be found at seafloor level and beneath the seafloor along the plate boundaries such as mid-ocean ridges and trenches. It is well known that at ocean ridges, hydrothermal fluid containing reduced compounds and minerals vent out from the seafloor. In contrast to the hydrothermal vents, focused flow containing reduced compounds, e.g., methane and hydrogen sulfide, gushing out from the seafloor can also be found along active and passive continental margins and around diapirs of serpentine and salt rock (halite) with no or less temperature anomalies compared to the ambient seawater. This fluid flow is called a cold seep.

The first cold seep was found at the Florida Escarpment off Oregon in 1984 by the submersible Alvin (Paull et al., 1984). The Alvin found a large number of alleged tube

worms and white clams which were thought to be highly endemic to hydrothermal vents. It turned out that there are fluid flows which contain reduced compounds and which support chemosynthesis-based life, similar to hydrothermal vents (Kulm et al., 1986).

Examples of the reduced compounds contained in cold seeps are methane and hydrogen sulfide. These compounds lead to extensive biogeochemical reaction when the fluid encounters oxic interstitial water which has penetrated into sediments from seawater. The reaction is mainly mediated by microbes as a way of obtaining chemosynthetic energy to synthesize their organic compounds. Primary production based on the chemosynthesis found in cold seeps results in the formation of characteristic life forms similar to those which can also be found in hydrothermal vents.

The important role played by methane in global warming is due to the fact that the greenhouse effect that results from it is more than 20 times that of carbon dioxide (Kvenvolden, 1988). Hence if we think of cold seeps as a pipe connecting the deep subsurface and the oceans, we can understand their importance in terms of global climate change and biogeochemical cycles at the sediment–water interface.

Distribution

Cold seeps are widely distributed along the active and passive continental margins of the world’s oceans (Figure 1; Sibuet and Olu, 1998; Levin, 2005). The depth range of a cold seep varies from shallow water less than 15 m (Montagna and Spies, 1985) to deep water more than 7,400 m in the Japan Trench (Fujikura et al., 1999).

The total number of cold seeps reported to date represent a minimum, because finding a cold seep is significantly more difficult than finding a hydrothermal vent. The difficulties of identification result from the natural characteristics of cold seeps which are difficult to observe by the use of a submersible or remote operated vehicle (ROV).

Natural characteristics of cold seeps

Cold seeps vary in accordance with their natural characteristics. Most cold seeps are very calm, i.e., the low seepage intensity and low fluid flow rate has no effect on the sea floor. The almost total absence of any temperature anomaly in relation to the ambient seawater also makes it difficult to distinguish the flow by visual observation. The occurrence of chemical anomalies is found over too narrow an area and the anomalies usually occur only in the sediment. Thus, this kind of calm cold seep, called a diffusive seep, is rather difficult to find on the basis of geological and geochemical signatures which exist only beneath the sea floor. One good indicator pointing to the existence of a cold seep is the occurrence of chemosynthesis-based life obtaining energy from the reduced compounds contained in the seep fluids (Sibuet and Olu, 1998). Such biota often comprises large bivalves and/or

Cold Seeps, Figure 1 Distribution of modern and ancient cold seeps and hydrothermal vents. (After Campbell, 2006.)

worm tubes which are clearly visible (Figure 2). However, seep-associated infaunal animals (i.e., animals living only in the sediments) and microorganisms are potentially difficult to detect.

Direct measurements of cold seep fluid chemistry started around the end of the last century (e.g., Tryon and Brown, 2001, 2004). The results show that the fluid pattern and rate of flow are more complex than was previously thought to be the case. Although most cold seeps are calm, there are some effusive and explosive cold seeps. When the saturation level of dissolved methane in sea water is exceeded, the excess methane forms gas bubbles (Figure 3) or gas hydrate (Figure 4) depending on the physical conditions. The bubbly gaseous methane can be found by visual observation (Figure 2) and also by hydroacoustic sounders, like a fisheries sonar (Figure 5; Paull et al., 2007; Aoyama and Matsumoto, 2009). The acoustic sounder makes it possible to see the plume due to the relatively low density of the methane bubbles compared to the ambient sea water. In waters off Niigata, Sea of Japan, methane bubble streams venting out from the sea floor at about 900 m water depth produce a plume

reaching to about 300 m below the sea surface (Figure 5; Aoyama and Matsumoto, 2009).

Cold seeps associated with a mud volcano or serpentine diapir show that the flow gushes out together with muddy sediment or brecciated serpentine rocks. It may also happen that methane erupts from the seafloor due to a pressure increase in the sediments caused by an accumulation of methane gas. Such an eruption forms chaotic structures of strata, like landslides, and crater-like topographically depressed areas, so-called pock marks. The size of a pock mark may vary from a few meters to a few hundred meters in diameter and from 1 m to 80 m in depth (Gay et al., 2006).

Pathway and migration of fluid flow

Generally, reduced compounds increase with depth in marine sediments. These reduced compounds can be oxidized by oxidants such as oxygen, nitrate, and sulfate and usually occur at a shallow depth under the sea floor. Although these reactions do also occur elsewhere below the sea floor, substantial reaction occurs in cold seeps

Cold Seeps, Figure 2 Cold seep in the Kuroshima Knoll, Okinawa, southwestern Japan. A dense colony of bathymodiolian bivalves, housing chemosynthetic microbes, covered the sea floor. Gushing out of gaseous bubbly methane can be seen. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

Cold Seeps, Figure 3 Collecting methane gas bubbles at a cold seep. ROV Hyper-dolphin collected the bubbly methane gas venting out from the cold seep in the waters off Joetsu, Sea of Japan. Putative shell-like gas hydrate covers each gas bubble. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

Cold Seeps, Figure 4 Outcrop observation of gas hydrate in the waters off Joetsu, Sea of Japan. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

because of the high amounts of reduced compounds brought up to the sea floor from the deep subsurface. Accumulation and migration of reduced compounds are required to form a cold seep.

The pore water containing reduced compounds favors migration through physically weak paths, e.g., faults, and permeable sediments. Tectonic stresses, e.g., plate subduction or diapirs, induce the formation of such pathways. Thus, occurrences of cold seeps are largely dependent on the tectonic background of the area concerned.

Cold seep pathways take the form of a fault or faulted anticline, salt or serpentine diapirs, or a cut bank of strata. These structures can be revealed by seismic profiles, direct observations of the outcrops in the ocean, and drill core samples with chemical profiles of the pore water (Figure 6; Moore et al., 1990, 2001).

Iodine radioisotopes (see entry *Isotopes, Radiogenic*) have recently been identified as a useful tool to determine the age of the strata from which the methane originated, as the iodine will be released at the same time as methane is generated from organic matter, and the diffusion rates of methane and iodine are very similar (Fehn et al., 2003).

For example, pore water from a cold seep in the Japan Sea passed through and probably originated from strata which sedimented during 30–20 Ma (Tomaru et al., 2007). Faults associated with cold seeps occur particularly on the landward wedge of subduction zones, e.g., the Barbados accretionary wedge, the Cascadia margin and the Japan Trench. Faults created by tectonic stress due to subduction of

Cold Seeps, Figure 5 Methane plumes observed by acoustic sounder at the Umitaka spur, off Joetsu, Sea of Japan. The plumes rose up from the sea floor at depths ranging from ca. 900 m to ca. 300 m. The horizontal axis indicates time. The vehicle obtaining the echogram ran from north to south. (Modified from Aoyama and Matusmoto (2009) (Patent no. US 7539081 B2, Seabed resource exploration system and seabed exploration method by Chiharu Aoyama).

plates play the role of physically weak pathways for the fluid flow. It may also happen that faults cut through a methane reservoir formed under impermeable strata, and the methane then migrates upward through the fault. Indeed, the direction formed by *Calymene* (bivalve) colonies, which mostly live in cold seeps and/or hydrothermal vents, is coincident with a theoretical stress fracture pattern caused by subduction tectonics (Ogawa et al., 1996).

The main driving forces of the migration of pore water containing reduced compounds are density differences and the compression of pore water by increasing pressure within the sediments. The buoyancy of gaseous and dissolved methane and light hydrocarbons in pore water is the main driving force for upward migration. Gaseous methane, the main hydrocarbon gas in the fluid flow, has a strong buoyancy, for example, the density of gaseous methane beneath 3–4 km of water is $200\text{--}300\text{ kg m}^{-3}$ compared with $1,024\text{ kg m}^{-3}$ for seawater (Clennell et al., 2000). Water in which methane is dissolved is also lighter than methane-free water. Thus, the pore water containing gaseous and dissolved methane potentially tends to migrate upward within permeable sediments. Entrapment of the fluid usually occurs where impermeable sediments are found. When strata composed of impermeable sediment are tilted, the fluid migrates within the permeable sediment in a lateral-upward direction directly beneath the impermeable strata. Thus, the hinge zone of an anticline is suitable for the accumulation of methane contained in pore water. Methane-rich fluids may further migrate upwards through faults that cut through the impermeable strata. The fluid also gushes out from outcrops where there is a break in the strata caused by erosion.

Cold Seeps, Figure 6 Interpreted seismic reflection obtained from accretionary prism, off Oregon. Rigid arrows indicate inferred flow paths for fluids. Direct measurements of bedding from the submersible Alvin correlate well with the seismic reflection lines. (After Moore et al., 1990.)

Increasing pressure arising from compaction due to continuous loading of sediments or tectonic stress squeezes out pore water containing reduced compounds into overlying strata. The increasing pressure causes not only pore water migration but also mud diapirs. This is why mud diapirs (or mud volcanoes) are often associated with methane or other reduced compounds.

Heating of the pore water is the other factor causing upward fluid migration. Heating occurs as a result of geothermal activities in the deep subsurface. After heating by geothermal activity in the deep subsurface, the temperature of the fluid drops during upward migration. Thus, the fluid temperature at sea floor level shows no or fewer anomalies in contrast to hydrothermal vents.

Migration of reduced compounds is also caused by diffusion. Although diffusion can be considered as a factor much less important than buoyancy and pressure increase, it is important for the penetration of oxidants from the sea water into sediments.

Chemistry of fluid flow

Major reduced compounds in the fluid flow in cold seeps are methane and other light hydrocarbons, hydrogen sulfide, ammonia, reduced iron, barium, and hydrogen (e.g., Tunnicliffe et al., 2003; Tryon and Brown, 2004). Methane is the most important by virtue of the fact that it is the most common hydrocarbon gas in marine sediments. Methane has a pronounced greenhouse effect and plays an important role both as an energy source and as a carbon source for microbes; furthermore, the anaerobic oxidation of methane (AOM) coupled with sulfate reduction produces hydrogen sulfide which acts as a major energy source for chemosynthesis-based ecosystems.

Elements contained in the fluid flow change with the depth of sediments, because the generation and consumption occur at different depths. Concentrations of reduced compounds generally increase in line with the depth of the sediments. Drastic changes in the chemical profile occur at shallower depths where the reduced compounds encounter oxidants. These reactions take place mainly within sediments, but it sometimes happens that the reduced compounds discharge directly into the sea water column. In such a case, the oxidation reactions take place within the water column.

The drastic chemical changes in cold seeps are generally responsible for substantial biological activities. Methane, the major reduced compound in a cold seep, is generated at a relatively deep subsurface level under anaerobic conditions. When a fluid flow containing methane migrates toward the sea floor and encounters oxidants such as oxygen and sulfate (see entry *Sulfur Cycle*) which penetrated into the sediment from oxic sea water, intensive biogeochemical reactions occur. The most important and extensive of these is AOM which occurs where the methane and sulfate coexist in anaerobic conditions. Following the AOM, oxidation of hydrogen sulfide, formation of pyrite (see entry *Iron Sulfide Formation*), and

precipitation of carbonate minerals occur. When the fluid flow gushes out into well-oxygenated conditions, aerobic oxidation of methane (*Methane Oxidation (Aerobic)*) occurs.

The origin of methane

There are several pathways for the generation of methane of which biogenic and thermogenic processes are the most important. In the case of the former, the methane is produced directly by microbes, and in the case of the latter, the methane is produced through the thermal degradation of organic compounds in the deep subsurface. Methane that is produced neither from organic material nor through organic processes can be found mainly along the edge of hydrothermal vent fields and above serpentine diapirs.

Biogenic methane

Biogenic methane is produced by microbes. The methanogenic microbes (methanogens) belong to the phylum Euryarchaeota within the domain Archaea. Methanogens are obligatory anaerobes, meaning that they live in an anoxic environment which usually occurred below the zone of sulfate reduction. The main substrates linked to the generation of methane are simple carbon-containing molecules such as carbon dioxide, formate, acetate, methanol, and methylamine (Whiticar, 1999). The two simple pathways of methanogenesis, i.e., carbonate reduction and acetate fermentation, are expressed as $\text{CO}_2 + 8\text{H}^+ \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$ and $\text{CH}_3\text{COOH} \rightarrow \text{CH}_4 + \text{CO}_2$, respectively. Archaeal methanogenesis promotes large fractionations of carbon isotopes. The stable carbon isotopic composition of methane produced by carbonate reduction generally ranges from -60 to -80‰ (vs. PDB), while the methane produced by the fermentation process ranges from -50 to -60‰ (vs. PDB; Whiticar, 1999). The methane is mostly a unitary hydrocarbon product of the biological process, whereas the thermogenic process explained below produces methane as well as other hydrocarbons such as ethane and propane. However, the recent suggestion that ethane and propane are also produced biologically (Hinrichs et al., 2006) upset the long-held concept of the origin of light hydrocarbons larger than methane, which were thought to be generated by the thermal degradation of organic matter only. The biogenic process is carried out at a relatively shallow depth compared to where thermogenic methane is produced. This is due to the presence of appropriate thermodynamic conditions, i.e., not too high a temperature and pressure, to permit microbial activities.

Thermogenic methane

The methane generated through the degradation of sedimentary organic matter as a result of thermodynamic conditions is called thermogenic methane (Kotelnikova, 2002). The rising temperature and pressure of sediments that accompany the increasing depth accelerates the

degradation of organic compounds. Thus, the production of thermogenic methane generally increases in proportion to the depth of the sediments, usually more than a few hundred meters below the seafloor. Contrarily, a high temperature inhibits microbial activities at a deep subsurface level, thus it follows that the dominant methane in the deep subsurface is thermogenically generated. This process produces not only methane but also ethane, propane, and other light hydrocarbons. There are fewer isotopic effects on carbon and hydrogen from methane produced by thermal maturation compared to biogenic methane. Thus, the carbon isotopic composition of thermogenic methane ranges from -20 to -50‰ (vs. PDB; Whiticar, 1999).

Abiogenic methane

Methane produced from inorganic matter through an inorganic process is called abiogenic methane. Such methane is thought to be generated through the processes of cooling and degassing of mafic igneous rocks and magma and the process of serpentinization of ultramafic rocks. Although the exact mechanism of abiogenic methane formation is still not fully understood, some abiogenic methane formation processes have been revealed (e.g., Horita and Berndt, 1999; Proskurowski et al., 2008). We can now say that abiogenic methane is probably the dominant methane source in hydrothermal vent systems especially along mid-ocean ridges and above serpentine diapirs.

Identification of the origin of methane

Looking specifically at the methane in cold seeps, it has been thought that this originated from the processes of biogenesis and/or thermogenesis. Most abiogenic methane will be found at hydrothermal vents and not at cold seeps except in the case of cold seeps associated with serpentine diapirs. Means of allowing us to estimate the origin of methane are a combination of analyses of the carbon isotopic compositions of the methane and the relative abundance of ethane and propane compared to the amount of methane included in fluid seepage (Schoell, 1988). Specifically, extremely negative carbon isotope values of methane, generally less than -50‰ (vs. PDB), with a high methane/(ethane + propane) ratio indicate that the methane was generated by a biogenic process. In contrast, less negative carbon isotopic composition, generally -20‰ to -50‰ (vs. PDB), with a relatively low methane/(ethane + propane) ratio indicates that the methane was generated by a thermogenic process.

Anaerobic oxidation of methane (AOM)

AOM is a key reaction at cold seeps. Although several probable reactions have been proposed (Valentine, 2002), the details of the AOM reaction are not yet clearly understood. What we can say is that the net reaction of the AOM is expressed as $\text{CH}_4 + \text{SO}_4^{2-} \rightarrow \text{HCO}_3^- + \text{HS}^- + \text{H}_2\text{O}$. Thus, the relative amounts of both sulfate and methane regulate the activity of AOM. This reaction occurs

widely in oceans because large amounts of sulfate are contained in sea water whereas the reaction will not occur in freshwater environments such as ponds, lakes, rivers, and rice fields because freshwater lacks sulfate (Whiticar, 1999). It has recently been recognized that AOM by sulfate reduction is carried out by consortia of anaerobic methane-oxidizing archaea and sulfate-reducing bacteria (Elvert et al., 1999; Boetius et al., 2000; Orphan et al., 2001, 2004). The anaerobic methane-oxidizing archaea (ANME) are found in three different phylogenetic clusters belonging to the Euryarchaeota, i.e., ANME-1, -2, and -3. It has also been revealed by genome analysis that methane is oxidized under anoxic conditions by means of a “reverse methanogenesis” process (Hallum et al., 2004). The ecology of each of these archaeal lineages (ANME-1, -2, and -3) differs from that of the others. Thus, the differences reflect their distribution pattern in cold seeps (Elvert et al., 2005; Knittel et al., 2005).

An important function of the AOM reaction is that it prevents the escape of methane, which has a pronounced greenhouse effect, from sediments into the ocean and the atmosphere. The carbon derived from methane is transformed into bicarbonate or carbonate ions. An increase in the ions leads to an increase in alkalinity and thus to the subsequent precipitation of carbonate minerals given the existence of calcium or other appropriate cations (explained below).

Oxidation of sulfides

The hydrogen sulfide (see entry *Sulfide Mineral Oxidation*), a byproduct of the AOM, is used for subsequent reactions. One is the oxidation of sulfides mediated by sulfur-oxidizing bacteria under (sub)oxic conditions, and the other is the formation of pyrite (see entry *Iron Sulfide Formation*) in anoxic conditions. Sulfur-oxidizing (thiotrophic) bacteria, such as *Beggiatoa* (qv), *Thiothrix*, and *Thioploca*, use the hydrogen sulfide as an electron donor and oxidize it by oxygen. The final product of the reaction is sulfate. Most sulfur-oxidizing bacteria are chemolithoautotrophs, but some can use organic compounds for their cell synthesis. The thiotrophic bacteria sometimes form white mats that cover the sea floor and some may live as symbiotic bacteria in animal tissues (e.g., in gills).

Aerobic oxidation of methane (qv)

The aerobic oxidation of methane (see entry *Methane Oxidation (Aerobic)*) is performed by methane-oxidizing (methanotrophic) bacteria, whereas archaea are responsible for AOM. When the methane is released directly into an oxic water column, it will be aerobically oxidized by these methanotrophs. However, in normal marine environments, methane is mostly oxidized anaerobically by AOM within the sediments. Aerobic oxidation of methane becomes important when methane vents out vigorously into oxic sea water.

Authigenic mineral precipitation in cold seeps (qv “microbial mineralization” and “microbially induced sedimentary structures”)

One result of the substantial biological reactions referred to above is the precipitation of several minerals. The minerals most commonly found in cold seeps are carbonate such as aragonite, high magnesian calcite, and low magnesian calcite. The precipitation of these carbonates occurred because of increasing alkalinity resulting from AOM. When AOM occurs at sea-floor level or above the sea floor in euxinic waters, reef-like carbonate build-ups may be formed on the sea floor, as in the Black Sea (Michaelis et al., 2002). Under an oxic water column, the reaction generally occurred within the sediment, thus the carbonate formed beneath the sea floor. At a shallower depth below the sea floor, aragonite and high magnesian calcite can be formed, whereas low magnesian calcite and dolomite are frequently found relatively deeper within the sediments (e.g., Takeuchi et al., 2007). Methane-derived carbonate bodies are sometimes exposed on the sea floor because of surface erosion. Then the carbonate may function as a hard substrate for sessile organisms or carbonate borers.

Pyrite is another common authigenic mineral found in cold seeps. Hydrogen sulfide produced as a result of AOM may combine with reduced iron to form monosulfide, i.e., a precursor of pyrite. Subsequent reaction of the precursor with elemental sulfur or sulfides promotes the formation of pyrite. It is commonly the case that the pyrite crystal aggregation forms a framboidal shape, a so-called framboidal pyrite (for details see Chapter *Iron Sulfide Formation*). The sulfur isotopic composition of pyrite inherits the composition of the hydrogen sulfide source and indicates whether or not the hydrogen sulfide derived from bacterial sulfate reduction (Peckmann and Thiel, 2004).

Relationship to methane gas hydrate

Cold seeps are frequently associated with gas hydrate (Figure 4) where the environment has appropriate physical conditions for gas hydrate formation. The main component of the gas hydrate is methane but carbon dioxide, ethane, and other gaseous molecules are also present. Gas hydrates form in low temperature – high pressure environments where the appropriate concentrations of methane exist (Zhang, 2003). Such environments are usually distributed in the deep sea around continental margins and in permafrost areas on land. The hydrate is one of the largest methane reservoirs in the world. It has been estimated that more than 2,100 Gt of methane are stored in gas hydrates.

Formation of a mass of methane gas hydrate usually occurs within sediments whereas methane rapidly escapes and does not readily accumulate in water columns. If a substantial amount of methane, e.g., bubbly methane gas, is released into a water column, gas hydrate may form as a thin shell on the surface of a gas bubble (Figure 3).

The depth limit of gas hydrate formation and occurrence in the sediments is usually determined by the local geothermal gradient. The gas hydrate itself may act as an impermeable barrier within the sediment. In this case, the methane gas, which has migrated from the deep subsurface, is trapped and accumulates beneath the gas hydrate layer.

The importance of the gas hydrate for cold seeps is that (1) pore water surrounding the methane gas hydrate has an oversaturated level of methane, and (2) the rapid dissociation of methane gas hydrate may result in an episodic increase of cold seeps and sometimes an eruption of methane. When methane-undersaturated water penetrates the sediment and comes into proximity with the gas hydrate, the gas hydrate dissociates so as to create a physical equilibrium between the pore water and the gas hydrate. When the pore water, after taking up a substantial amount of methane, migrates further upward, a continuous methane supply is established between the methane gas hydrate reservoir and the sea floor.

Episodic emission of methane because of the dissociation of methane gas hydrate occurs, for example, in cases where the sea level decreases at the beginning of a glacial period or increasing sea water temperature because of global warming (e.g., Judd et al., 2002). The dissociation of gas hydrates may cause instability of the sea floor inducing landslides (Buffett, 2000). Such an underwater landslide results in additional lowering of pressure and may produce further dissociation of gas hydrate. It should be noted that the meaning of the existence of methane gas hydrate is that the area has large potential for the generation and/or accumulation of methane.

Because the density of gas hydrate is lower than that of sea water, the gas hydrate itself tends to rise upwards. Thus, an insufficient mixture of sediment in the gas hydrate and/or insufficient loading by overlain sediments causes the release of a mass of gas hydrate into a water column.

Ecosystem established at cold seeps – chemosynthesis-based ecosystems

Cold seeps can be considered as chemosynthesis-based ecosystems that support a large amount of life in deep seas (Figures 2 and 7; Sibuet and Olu, 1998). The main primary producers of the ecosystem found in cold seeps are chemoautotrophic microbes, such as sulfur-oxidizing bacteria. For the sulfur-oxidizing bacteria, hydrogen sulfide has the role of an electron acceptor, oxygen that of an electron donor, and carbon dioxide that of a carbon source. Such microbes that metabolize via the chemical reaction of inorganic compounds with an inorganic carbon source are called chemolithoautotrophs. An ecosystem based on chemoautotrophy is called a chemosynthesis-based ecosystem. This kind of ecosystem is a counterpart to the photosynthetic ecosystem found on the surface of the Earth. Chemosynthetic ecosystems establish themselves especially in areas where light does not penetrate such as the

Cold Seeps, Figure 7 Chemosynthesis-based community composed of a dense accumulation of *Bathymodiolus* (mytilid bivalves) from Kuroshima Knoll, off Okinawa, southwest of Japan. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

deep sea and the subsurface below the sea floor. Within these settings, chemosynthesis-based ecosystems particularly flourish at cold seeps and hydrothermal vents because these are environments where large amounts of reduced compounds encounter oxic waters.

With chemosynthetic microbes as a basis, heterotrophic microbes and animals flourish in cold seeps as members of the chemosynthetic ecosystem. In order to flourish in a oxygen-poor cold seep environment which is instead rich in toxic substances such as hydrogen sulfide, the animals found there often have a detoxification system (Felbeck et al., 1985). Most animals living in cold seeps house chemosynthetic bacteria, such as sulfur-oxidizing bacteria and methane-oxidizing bacteria, and obtain organic matter from those symbionts. These symbiotic chemosynthetic bacteria are called as chemosymbiotic bacteria. The animals living in cold seeps are generally endemic at a higher taxon level and diverge from the animals belonging to photosynthetic ecosystems. Major animals living in a cold seep environment are vesicomyid, mytilid, thyasirid, lucinid, and solemyid bivalves, provannid, acmaeid and neomphalid gastropods, and vestimentiferan tube worms. Crabs, sea urchins, sponges, and barnacles are occasionally found as minor faunal elements. Nectobenthic animals, i.e., animals that can live near the sea floor, such as hydrothermal vent shrimps, are relatively fewer in number at cold seeps than in hydrothermal vent fields. This is because the reduced compounds, their energy source, are often consumed already within the sediments, and only occasionally appear above the sea floor. In contrast, infaunal animals, i.e., animals that live in the sediment, are more abundant in cold seeps than in hydrothermal vents, because the cold seeps are usually covered by rich soft sediments whereas fresh

(recently formed) hard igneous rocks are exposed at hydrothermal vent fields.

The biotic composition of cold seeps is controlled by physicochemical factors including the quantity of reduced compounds such as methane and hydrogen sulfides. One good example of the biotic elements controlled by methane accumulations is seen at Hydrate Ridge (Cascadia Margin, off Oregon). *Beggiatoa* (sulfur-oxidizing bacteria) mats, *Calyptogena* (vesicomyid bivalve), and *Acharax* (solemyid bivalve) all flourish in this cold seep area in a zoned distribution. A large concentration of hydrogen sulfide was detected in the *Beggiatoa* zone, decreasing toward the *Acharax* zone through the *Calyptogena* zone (Sahling et al., 2002). A similar regulation of distribution caused by the concentration of hydrogen sulfide occurred at the species level. Two species of *Calyptogena* (bivalve), *C. kilmeri* and *C. pacifica*, coexisted in a cold seep but they were roughly segregated. The *C. kilmeri* lived where there was a much higher concentration of hydrogen sulfide and the other lived where the concentration of hydrogen sulfide was much lower (Barry et al., 1997).

The biotic component that lives in cold seep environments looks similar to those found in other reduced environments such as hydrothermal vents, sunken vertebrate carcasses, and driftwood (see Chapter *Whale and Wood Falls*). Actually, the components are mostly the same at a higher taxonomic level (i.e., genus or family level), although they are restricted to living in a single type of habitat at the species level (Peck et al., 1997), except for vertebrate carcasses (Smith and Baco, 2003). Twenty species found in a cold seep environment also live on/around vertebrate carcasses. Thus, vertebrate carcasses may play a role as a dispersal stepping stone prior to living in a cold seep at least for some species. It is generally thought that the macro organisms in hydrothermal vent environments have evolved from cold seep species (Hecker, 1985; McLean 1985; Craddock et al., 1995). In addition, molecular data indicate that mytilid bivalves living in a cold seep environment adapt to such a reduced environment via whale carcasses as an evolutionary stepping stone (Distel et al., 2000; Smith and Baco, 2003).

Ancient cold seeps

Recognition of ancient cold seeps

Numerous ancient cold seeps dating from various ages have been found in a variety of tectonic settings (Figures 1 and 8; see review in Campbell, 2006). The identification of ancient cold seeps depends on revealing features which indicate the presence of methane and other hydrocarbons which escaped from the sea floor. In order to make these features evident, a comprehensive approach based on geological, geochemical, and paleontological techniques is a primary requirement.

It is well known that carbonate minerals are forming in modern cold seep environments as a result of increased alkalinity due to AOM (Ritger et al., 1987; Aharon,

Cold Seeps, Figure 8 Late Cretaceous cold seep deposit (*above*) and dense accumulation of lucinid bivalves associated with the carbonate (*below*) from South Dakota, USA. The carbonate rock was induced by anaerobic oxidation of methane at a late Cretaceous active cold seep in the Western Interior Seaway, located in the eastern part of what is today the Rocky Mountains in northwestern America.

2000). Methane-derived carbonates are potentially imprinted with environmental information concerning the location where they were formed. Shapes, textures, and imprinted chemical signatures of modern cold seep

deposits can be seen as a good analog facilitating the recognition of ancient cold seeps. A conduit pipe such as a carbonate chimney (Takeuchi et al., 2007), although they are generally formed under the sea floor in contrast to chimneys at hydrothermal vents, is a good example indicating the route of fluid. Cold seep carbonates often have chaotic fractured structures. The fracture is usually ductile and/or accompanied by brittle sediment deformations. The deformations are probably due to active fluid venting. Microbially induced carbonate cements, e.g., clotted fabrics and isopachous fibrous cements, are frequently found in the carbonate. The influence of methane and microbial activity can be detected by further biogeochemical analysis (Peckmann and Thiel, 2004).

The carbon isotopic compositions of the carbonate reflect the values of the carbon source. Methane, the main gaseous component of cold seeps, generally shows negative carbon isotopic compositions in the case of thermogenic and biogenic methane (see above). The carbon isotopic compositions of thermogenic and biogenic methane commonly range from -30 to -50‰ and -50 to -80‰ (vs. PDB), respectively, and are thus distinguished from other carbon sources in the marine environment. These values will be imprinted at roughly the same level in the carbon isotopic compositions of the methane-derived carbonate. Considering that the $\delta^{13}\text{C}$ -values of carbonate are often somewhat higher than the values of the source methane because of the admixture of other carbon sources (Peckmann and Thiel, 2004), values ca. lower than -30‰ (vs. PDB) suggest that a major portion of the carbonate carbon is derived from methane.

Lipid biomarkers provide information on ancient microbial activities. It has been revealed that AOM is mediated by microbial consortia composed of archaea and sulfate-reducing bacteria (Orphan et al., 2002). Cell membrane lipids produced by those microbes have a strong propensity to be preserved in sediments (Peckmann and Thiel, 2004). Analyzing the carbon isotopic composition of each of these biomarkers (see entry *Biomarkers (Organic, Compound-Specific Isotopes)*) tells us whether or not the microbes used methane as the carbon source for their biosynthesis. The carbon isotopic compositions of lipids derived from methanotrophic microbes sometimes reach as low as -120‰ or even lower. On the basis of this information, the presence of isotopically depleted lipid biomarkers derived from archaea will be a good indicator for the occurrence of AOM (Elvert et al., 2005).

Oldest cold seep

Ancient cold seeps with chemosymbiotic macrofossils have been traced back to at least Silurian (Barbieri et al., 2004). As it is difficult to find and recognize ancient cold seeps without macrofossils, there is practically no record of older cold seeps. However, a possible cold seep occurring after the severe glacial period around 600 Ma, i.e., the period known as “Snowball Earth,” has recently been

proposed. The evidence for a cold seep related to the dissociation of methane gas hydrate is the strongly negative carbon isotopic composition of the “cap carbonate” from south China (Jiang et al., 2003). However, cap carbonates on a glacial deposit formed around 600 Ma are widely distributed throughout the world. If all the cap carbonates were formed under the influence of dissociating methane gas hydrate, numerous cold seeps would have appeared at that time. It is easy to imagine that widespread cold seeps existed in the Precambrian because biogenic methane already existed at 3.5 Ga (Ueno et al., 2006). The apparent lack of cold seeps in the Precambrian, apart from the cap carbonate, is probably due to their having been overlooked because of a lack of associated macro fossils.

Changes in cold seeps through time

The number of cold seeps varies through the Phanerozoic. In the Paleozoic, there are only five ancient cold seep localities. In spite of the fact that a stratigraphic change in carbon isotope ratios shows a global negative shift at the Permian/Triassic boundary, probably caused by the release of a large amount of methane into the ocean and the atmosphere, probably from methane gas hydrate, there are no records of ancient cold seeps from the Permian and Triassic. However, the number of records of ancient cold seeps in post-Triassic marine sediments has increased. More than 15 localities have been found in the Mesozoic and in an abundance of localities, more than a dozen, from the Cenozoic (Campbell, 2006). The cause of the drastic increase in cold seeps since the late Mesozoic might be due to an increase of organic flux into sediments resulting from increasing planktonic productivity and diversity during the Mesozoic Era (Tappan and Loeblich, 1973; COSOD II, 1987) leading to increasing generation of methane in marine sediments.

The biotic components of cold seeps changed through the Phanerozoic (Campbell and Bottjer, 1995; Little and Vrijenhoek, 2003). Mollusks are the most dominant organism in modern cold seeps, despite the dominance of brachiopods in the Paleozoic and mid-Mesozoic. The brachiopods were replaced by mollusks, mainly by bivalves, in the late Mesozoic (Campbell and Bottjer, 1995; Kiel and Peckmann, 2008). The last abundant occurrence of brachiopods in cold seeps is found from the Campanian, late Cretaceous (ca. 80 Ma), from the Omagari, Hokkaido, Japan (Hikida et al., 2003; Kaim et al., 2010). Vesicomyid and bathymodiolian bivalves, which flourished in modern cold seeps, entered the cold seep environment during the Eocene (Ca. 40 Ma; Kiel, 2006; Amano and Kiel, 2007; Amano et al., 2008). It should be noted that the fossil record of vesicomyid bivalves has recently been reexamined and its origin changed from Cretaceous to Eocene (Amano and Kiel, 2007; Amano et al., 2008; Kiel et al., 2008). Most living molluscan genera which lived in ancient cold seeps originated in the late Mesozoic to Paleogene (see basic data in Kiel and Little, 2006 and updated data in Amano et al.,

2007; Jenkins et al., 2007; Campbell et al., 2008; Kaim et al., 2008; Kiel et al., 2008; Kaim et al., 2009).

Impact on climate change

Judd et al. (2002), indicate that the input of greenhouse gases from the sea floor into the world's oceanic and atmospheric systems may be an important component of the atmospheric carbon budget, because the greenhouse potential of methane is more than 20 times that of carbon dioxide. A catastrophic release of methane may therefore produce global climate changes. Such an event due to the rapid escape of methane into the atmosphere happened at the Paleocene–Eocene boundary (ca. 55.5 Ma). At that time, the rapid dissociation of methane hydrate and subsequent release of methane into the atmosphere resulted in global warming and an increase of 6°C in the sea surface temperature (Dickens et al., 1995). A similar methane release outburst is thought to have occurred at the end-Permian forming one of the biggest known biodiversity crises (see entry *Critical Intervals in Earth History*) (Ryskin, 2003; Retallack and Krull, 2006). Kennet et al. (2002) proposed that the periodic glacial-interglacial cycle during Quaternary was controlled by the decomposition of methane gas hydrate and the subsequent release of methane gas into the atmosphere. Evidence of these methane releases comes mostly from carbon isotopic anomalies which were recorded in carbonate and organic material. The release of isotopically depleted biogenic methane induces negative carbon isotope excursions because of the transfer of ¹³C-depleted carbon from methane to carbon dioxide.

Summary

Cold seeps have been the object of considerable attention because of their role as a connecting pipe between the lithosphere, hydrosphere, and biosphere on the Earth. Reduced compounds contained in cold seep fluid result in substantial biogeochemical reactions. The establishment of a cold seep requires specific geological and biological background conditions, such as tectonic stress to make a route for the fluid, sedimentary organic matter supply to provide a source of methane and other hydrocarbons, microbial and/or geothermal activities to form the hydrocarbons, and microbial activities accounting for the oxidation of reduced compounds. Revealing the processes and mechanisms has largely progressed during the last 2 decades. For example, it was revealed at the time of the transition from the twentieth to the twenty-first century that anaerobic methane-oxidizing archaea and sulfate-reducing bacteria are responsible for the anaerobic oxidation of methane. However, there are still many questions about cold seeps that remain unresolved, e.g., the long-term behavior of cold seeps, response to climate change and details of various biological processes and mechanisms. Gaining an understanding of cold seeps is a primary requirement because a cold seep provides a condensed version of

geobiochemical processes related to methane. Thus, the knowledge that we can obtain from the research on cold seep may help us to understand a much wider range of geobiological phenomena taking place on Earth.

Furthermore, methane, the main component contained in cold seep fluids, has a potentially large effect on global warming. It is evident from several geological records through the Phanerozoic that dissociation of methane gas hydrate has drastic effects in terms of global climate change. Methane is also attractive to human beings because of its large potential as a future energy source. In fact, the methane amount stored in gas hydrate beneath the sea floor and permafrost is more than 2,100 Gt. However, as noted above, methane has a tremendous potential to bring about global climate change on the Earth. Thus, any form of intervention in the natural gases in marine sediments should be carefully carried out on the basis of sufficient knowledge of what will happen when the methane is released from the sea floor. Adopting this stance implies a very strong requirement to reveal the entire range of processes and mechanisms within a cold seep.

COMETS

Comets are primitive conglomerates of the solar system containing a mixture of frozen gases, refractory grains, and carbonaceous particles rich in biogenic elements (Llorca, 2005). The great variety of organic molecules carried by comets could have played a major role in prebiotic processes prior to the appearance of microorganisms. Please refer to entries “*Astrobiology*,” “*Asteroid and Comet Impacts*,” “*Meteoritics*,” and “*Origin of Life*.”

COMMENSALISM

Commensalism is a form of a symbiosis, in which one organism benefits and the other remains unaffected. See entry “*Symbiosis*” for further reading.

COMMUNITY

All populations in a habitat. The composition of a community and the abundance of its members is referred to as community structure. See entry “*Microbial Communities, Structure, and Function*” for further reading.

COPPER

Stephan M. Kraemer
 University of Vienna, Vienna, Austria

Definition

Copper (Cu) is a transition metal that serves as an essential nutrient to eukaryotes and many prokaryotes due to its many functions in copper enzymes. At elevated concentrations, Cu is toxic and the many industrial uses of copper

and its release to the environment has resulted in Cu pollution in soils and surface waters.

Properties: Copper has two stable isotopes ^{63}Cu and ^{65}Cu with a natural abundance of 69.17 and 30.83, respectively, and a standard atomic weight of 63.546 (Coplen et al., 2002; Wieser, 2007). The copper concentration in the bulk continental crust, in the oceanic crust, and in soils is estimated to be 27 ppm (Rudnick and Gao, 2003), 78 ppm (Wedepohl and Hartmann, 1994), and 39 ppm (Han et al., 2002), respectively. The concentrations of copper in unpolluted seawater is typically around 0.3 ppb and in river water, 1.5 ppb (Gaillardet et al., 2003). The world average concentration of copper in rivers has been estimated as 23.6 nM Cu dissolved load and 100 ppm Cu suspended particulate load (Martin et al., 1993; Martin and Meybeck, 1979; Martin and Thomas, 1994). In natural systems, it occurs in the Cu(I) (cuprous) or Cu(II) (cupric) redox states and rarely as elemental copper. The standard redox potential of the aqueous Cu(I)/Cu(II) couple is at 0.34 V, but the actual redox potential depends strongly on its coordinative environment. This is exploited by organisms using Cu as reactive center of reductases with high redox potentials between +0.2 and +0.8 V.

Copper toxicity: Due to its toxicity to humans, the US-EPA maximum contaminant level goals and EU standards for copper in drinking water has been set at 1.3 (USEPA, 1991) and 2 mg/l (EU, 1998), respectively. Copper is also toxic to marine and terrestrial prokaryotic and eukaryotic organisms (Flemming and Trevors, 1989; Gledhill et al., 1997). Its toxicity derives from its redox reactions producing radical ions similar to Fenton chemistry causing oxidative stress. Phytochelatins (plants) and metallothioneins (animals, fungi) are intracellular metal binding proteins that play an important role in detoxification and homeostasis of Cu and other metal ions.

Copper as a nutrient: Copper-containing oxidoreductase enzymes are widespread among prokaryotic and eukaryotic organisms and mediate important biogeochemical processes, including nitrification, denitrification, and methane oxidation. Examples are particulate methane monooxygenase, ammonia monooxygenase, nitrite reductase, cytochrome *c* oxidase, and superoxide dismutase. It has been suggested that Cu-bearing reductases evolved only after the oxygenation of the Earth atmosphere, considering the low solubility of Cu in sulfidic environments and the high redox potential of organically bound Cu(I)/Cu(II) up to the limit of the stability field of water (Frausto da Silva and Williams, 2001). Copper is part of a metalloenzyme involved in the uptake of iron by diatoms so that a Cu/Fe co-limitation of primary productivity in the ocean is conceivable (Maldonado et al., 2006; Peers et al., 2005). Recently, it was discovered that some methanotrophic bacteria possess a high-affinity Cu uptake system involving methanobactin, a structurally distinct chromopeptide metallophore analogous to iron-specific siderophores (DiSpirito et al., 1998). This highlights the potential role of copper availability and copper uptake in regulating biogeochemical cycles.

COSMIC MOLECULAR CLOUDS

Joachim Reitner

University of Göttingen, Göttingen, Germany

Synonyms

Complex molecular clouds; Interstellar clouds; Interstellar dust and molecules; Molecular clouds

Definition

A cosmic molecular cloud is an accumulation of cosmic matter that is composed of organic and inorganic molecules. The dust grains in a cosmic molecular cloud are mainly composed of crystalline silicates (Watson et al., 2009) covered with ice of H_2O , NH_3 , and CO_2 . The main molecule constituent is H_2 -He, but other molecules also occur, e.g., NH_3 , CO , and complex organic molecules.

Cosmic molecular clouds are denser than the interstellar medium, with gas densities ranging from about 10 molecules per cm^3 on large scales to over 10^6 molecules per cm^3 in cloud cores. These cores are very cold, with temperatures ranging from 8 to 20 K. New stars and protoplanetary discs are formed, when it comes to a gravitational collapse of cosmic molecular clouds. Via nucleosynthesis, these stars produce elements, which may constitute organic molecules (e.g., H, C, N, O, S, P). When

stars burn out, they collapse either via catastrophic explosions or by forming expanding shells, thereby recycling modified material back into the interstellar space and, thus, forming new cosmic molecular clouds (Boss, 2004). Some of the interstellar clouds are enriched in prebiotic organic molecules. These molecules are found in cosmic matter, chondritic asteroids/meteorites, and cosmic dust particles.

Based on spectroscopic wavelength analyses, more than 120 different complex organic molecules could be detected within cosmic molecular clouds, including common PAHs (polycyclic aromatic hydrocarbons), amino acids, sugars ("polyols"), hydrogen cyanide (HCN), and formic acid (Figure 1) (Ehrenfreund and Menten, 2001). The largest organic molecules so far reported from cosmic molecular clouds are cyanodecapentayne (HC_{11}N) and diethyl ether ($\text{C}_2\text{H}_5)_2\text{O}$. Not all of these molecules are part of the gaseous phase, but the more complex ones are related with cosmic dust particles. A well studied cosmic molecular cloud is the Sagittarius B cloud, where the most complex organic molecules like ethyl cyanide, acetone, glycine, acetic acid, and glycolaldehyde were detected (Hollis et al., 2000; Snyder, 1997). Glycolaldehyde may react with ribose to form a molecule, which is a major constituent of RNA. It was hypothesized that organic molecules within a cosmic molecular cloud are formed on 1–2 μm -sized dust grains, e.g., via photochemical reactions. These dust grains have a distinctive shell-like structure. An inner core of silicates is covered by an inner rim

Cosmic Molecular Clouds, Figure 1 Interstellar space with the occurrence of different organic molecules. (From Ehrenfreund and Charnley, 2000.)

containing complex organic compounds like amino acids, “polyols,” and carbonaceous matter such as hydrogenated amorphous carbon or kerogen-like material. The inner rim is covered by an outer rim consisting of “dirty” ice. In that icy outer rim, due to the heavy ultraviolet radiation, radicals are formed and H_2 is dissociated in monoatomic H that may react with other radicals to form organic molecules (Sorrell, 2001; Pearson et al., 2002). An important finding obtained with the Hubble Space Telescope was the observation of protoplanetary discs in the Orion cloud (Megeath et al., 2005). The size of these discs is more or less similar to our solar system. During solar system formation, an interstellar cloud becomes the building block, from which planets, asteroids, and comets form. Comets and carbonaceous chondrites are chemically very similar to star-forming interstellar clouds and are relics of them (Busemann et al., 2006; Wickramasinghe et al., 2009). They carry pristine primitive organic matter and represent a plausible source of prebiotic organic matter on the late Hadean early Earth. The stable isotope compositions of organic matter, e.g., from the Murchison carbonaceous chondrite (CM2), provide clear evidence that the organic matter was formed under conditions in stellar clouds and not on Earth (Sephton et al., 2003, see entry “*Meteoritics*” for further reading). External delivery of water and organic compounds is widely accepted as the origin of pristine earth-related organic matter (Wickramasinghe, 2010) and may have pushed the start of early life with the first microbial organism – *LUCA* – *Last Universal Common Ancestor* (Hoenigsberg, 2003).

CRITICAL INTERVALS IN EARTH HISTORY

Frank Wiese, Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

In our human understandings of time, Darwinian evolution is something, which happens very slowly. Consulting the (biogeochemical) fossil record, we notice periods in life’s history, which are characterized by slow and continuous evolution, successive background extinction, and equally successive new speciations. On the other hand, we see also periods, during which a sudden occurrence of new groups and its rapid radiation and dispersal can be seen in the fossil record. *Vice versa*, we also recognize catastrophic extinction events (mass extinctions; see below), reducing the number of known taxa dramatically within a very short time of only thousands of years or even much less.

Among these intervals were phases, in which comparatively short-termed (in a geological sense) pulses of evolution resulted in significant and irreversible evolutionary innovations, which opened new paleobiological pathways, affecting the abiotic and biotic evolutionary landscape likewise. These intervals are what we understand as main critical intervals in earth’s history here, and we believe that three periods merit this designation. These are the

Great Oxygenation Event or the Great Oxidation Event, respectively (GOE, ca. 2.4 Ga), the Cambrian Explosion around 524 Ma (Lower Cambrian), and the evolution of land plants from the Middle Ordovician on (ca. 463 Ma; Figure 1).

Critical Intervals in Earth History, Figure 1 Overview over the most significant critical (late Proterozoic to terminal Cretaceous) intervals considered in the text, and their stratigraphical position. Blue: diversification; dark: extinction.

Critical intervals of subordinate significance are mass extinction events. It is clear that any of these phases of mass extinction reflect severe perturbation in the global ecosystems, and there is no doubt that the biotic recovery from mass extinctions is also a critical period in the regeneration of the biosphere. However, when carefully considering the most significant phases of mass extinction in the Phanerozoic (the "Big Five"; Figure 1), we see that its aftermaths never resulted in the evolution of any new clades. Although critically for the fauna extinct, new taxa always developed in a saturated evolutionary landscape, where no space was for innovations at a clade's scale. These events, thus, represent "merely" a convulsion of the taxonomic inventory and are regarded here as subordinate critical intervals.

The study of critical intervals in the history of life aims at the mapping of the paleobiological and geological changes during these intervals, the interaction between the both, and the attempt to extract possible complex triggering mechanisms for the phenological expression in the (biogeochemical) fossil record within its geological framework. The study of critical intervals is, thus, an ideal example of how geobiology is embedded in interdisciplinary research of classic paleontology, genetics, bio- and isotope geochemistry as well as sedimentary geology, to name some of the disciplines inevitably applied.

Great Oxygenation Event, ca. 2.4 Ga (Great Oxidation Event)

Definition

Sedimentological and geochemical data indicate that the atmosphere became suddenly oxygenated up to a pO_2 of ca. 1% of present atmospheric level (PAL) around ~2.4 Ga (Kump, 2008; Figure 2). This period is called the "Great Oxygenation Event" or the "Great Oxidation Event" (GOE). Thus, it marks the boundary between an oxygen-free and an oxygenized world. The GOE approximates stratigraphically the boundary between the Archean and the Proterozoic (2.5 Ga).

Evidences

The evidence for atmospheric oxygenation results from various independent sources, which also provide controversial data (see compilations in Holland, 2006; Falkowski and Godfrey, 2009; Figure 2).

Sedimentological aspects: Prior to the GOE, detrital pyrite, uraninite, and siderite are known from siliciclastic fluvial sediments – minerals that would have been oxidized under the presence of O_2 either in the atmosphere or water – and this clearly indicates the lack of any free oxygen. There are no records of these minerals younger than 2.5–2.3 Ga. Around 2.4 Ga, the first red beds developed in the continental areas, resulting from dispersedly distributed ferric oxide in the sediments, which only could have developed by oxygenation of ferrous iron under the presence of free atmospheric O_2 . A while later, the mineral glauconite (containing ferric iron) occurred for the first time.

The occurrence of banded iron formations (BIFs) from the early Archean on (ca. 3.8 Ga) with its peak occurrence

Critical Intervals in Earth History, Figure 2 Compilation of sedimentological, mineralogical, biogeochemical, paleobiological and climatical trends with an estimate of the O₂ evolution throughout the Archean through Phanerozoic (based on the references cited in the text).

at ca. 2.6 Ga, bearing large amounts of ferric iron, were previously thought to correlate positively with the occurrence of oxygen (see overview in Klein, 2005). However, as shown by Kappler et al. (2005), the precipitation of ferric oxides by anoxygenic phototrophic Fe(II)-oxidizing bacteria could also explain the development of BIFs, which then is not indicative of any O₂ availability.

Geochemical evidence: Geochemically, the period around 2.4 Ga is characterized by the establishment of mass dependent sulfur isotope fractionation (Bekker et al., 2004; Farquhar and Wing, 2003) and a first enrichment of molybdenum in black shales (Scott et al., 2008), both indicative of a progressively oxidized atmosphere. In addition, chromium isotope fractionation points at slightly elevated O₂ levels even earlier than the GOE already at ca. 2.8–2.6 Ga (Frei et al., 2009).

Possible causes for the GOE

There are a variety of models that try to explain the GOE.

Onset of oxygenic photosynthesis/anaerobic oxidation of methane (AOM) (2.7–2.6 Ga). Anaerobic methanogenesis

by archaea (*via* methyl-CoM reductase) was responsible for an estimated atmospheric methane concentration of 1,000 ppm and extreme greenhouse conditions in the early atmosphere. The rise of oxygenic photosynthesis by cyanophyta (at ~2.45 Ga) as suggested by biomarker evidence (Buick, 2008), and the onset of AOM by sulfate reduction (at ~2.7 Ga; Hinrichs and Boetius, 2002) resulted in a significant withdrawal of CO₂ and CH₄ from, and an enrichment of O₂ in the atmosphere. Anbar et al. (2007) proposed “a whiff of oxygen” some ca. 90 Ma before the GOE, and Kaufman et al. (2007), based on sulfur isotopes, suggested slightly oxic conditions in the ocean prior to oxygenation of the atmosphere, but the sudden oxygenation event at 2.4 Ga has also been considered as a direct result of increased microbial activity reaching a ‘critical point’ by some scientists.

Time lag: An alternative approach derives from the assumption that oxygenic photosynthesis had already been established around 3.2 Ga (deduced from kerogen-rich black shales) or even 3.8 Ga (deduced from U–Th–Pb isotopy; see Buick, 2008 for discussion). The time lag

between the onset of oxygenic photosynthesis and the GOE has been explained by two models. Konhauser et al. (2009) observed a decrease in nickel concentration of ocean waters around 2.4 Ga. As nickel is a crucial element in several enzymes of methanogens, a decline would have severely dropped its activity (nickel famine). The stagnation of biogenic methane supply would then have favored a rapid increase of environmental oxygenation. Goldblatt et al. (2006) proposed, based on modeling, an alternative explanation. Assuming the onset of oxygenic photosynthesis at 2.7 Ga, the 300 Ma time-lag is explained by the bistability of the atmospheric oxygen system. A low oxygen steady state system existed at oxygen levels around and below 10^{-5} PAL prior to the GOE. With oxygen levels higher than 10^{-5} PAL, UV shielding becomes more efficient, which resulted in a nonlinear increase of atmospheric oxygen's lifetime and thus, oxygen content. The high-oxygen steady-state system stabilized at values larger than 5×10^{-3} PAL.

Concluding remarks

Even though the timing of the onset of oxygenic photosynthesis is controversially debated, sedimentological and geochemical data clearly point at a time around 2.4 Ga, where the atmosphere became slightly oxygenized with values of ca. $>10^{-5}$ PAL. The presumably microbially induced severe drawdown of the greenhouse gases CH_4 and CO_2 and the increase of O_2 resulted in a temperature drop of estimated 4–9°C (Goldblatt et al., 2006), leading directly to the climate disaster of the Paleoproterozoic Huronian snowball earth glaciations at ca. 2.3–2.1 Ga (Kopp et al., 2005).

The GOE is also regarded as an oxygen catastrophe or oxygen crisis. In fact, from the moment on, when oxygenized environments in the oceans and in/on the ocean floors developed, these oxic environments (which progressively increased) were no longer habitable for anoxic microorganisms. Thus, the GOE also marks a first fundamental and irreversible turnover of shelf microbial community structure and, thus, a first truly critical interval in Earth's history.

The Cambrian Explosion

Definition

The Cambrian “Explosion” marks a sudden outburst of morphological disparity (distinctness) and diversity among metazoans during the early Cambrian. Starting around ca. 524 Ma, the number of known genera increased within roughly 10 Ma from something about 200 genera in the Tommotian (Lower Cambrian) to ca. 1,200 genera in the Botomian (highest Lower Cambrian, Figure 3). During this interval, all modern phyla occurred in the sedimentary record, including the vertebrates, thus, being the birth of the “tree of animals” (Shu, 2006). An overview on the ecology of the Cambrian Explosion is given by Zhuravlev and Riding (2001).

The way to the Cambrian Explosion

The explosion of life is impressively documented by the rich and excellently preserved faunas in a number of important Cambrian “fossilagerstätten,” which opened a preservation window to this early period of metazoan evolution and diversification. Maybe, the most famous ones are the Chengjiang and Sirius Passet biota (Lower Cambrian; Figures 4 and 5) and the Burgess Shale biota (Middle Cambrian; Figure 3). There have been repeated discussions in the past, whether we see a true pulse of evolution or whether we face merely exceptional preservational hot-spots, and based on calibration of the molecular clock some authors suggest increasing disparity already around 1 Ga (e.g., Blair and Hedges, 2004). Other molecular clock dating suggests cryptic evolution of the Metazoa in the Cryogenian, but a first radiation pulse occurred at ca. 635–542 My (Peterson et al., 2008). This approximates roughly the first occurrence of animal macrofossils at 575 Ma. However, at the moment, the literature data suggest a common understanding that we see a true expression of metazoan radiation in the fossil record. To appreciate this event in its significance fully, it is desirable to highlight it in its evolutionary context from the first occurrence of larger animal body fossils and trace fossils from ca. 575 Ma on (Figure 3).

The post-GOE times from 2.4 Ga on were a period of evolutionary stasis – the “boring billion” of Kerr (2005) – in which stromatolites had their abundance and diversity peak from ca. 2.0 to 1.0 Ga. Either complex Cyanophyta colonies or possibly the first eukaryotic algae (*Grypania*) occurred by 2.0 Ga, and the first red algae are known since 1.2 Ga (Butterfield et al., 1990). The rise of complex animal life (Metazoa: Parazoa) is dated by some authors around 1 Ga, based on carbonate rock texture (Neuweiler et al., 2009) or by molecular clock dating (e.g., Hedges et al., 2004). After the last Snowball Earth glaciation around 580 Ma (see Hoffman and Schrag, 2002 on the *Snowball Earth* theory), enigmatic body fossil of organisms with unknown taxonomic affinities, the Vendobionta (reaching already sizes up to 2 m!), occurred worldwide at ca. 575 Ma. The Vendobionta show a typical “quilt” bauplan (Figure 6), and they are intimately associated with microbial mats (“elephant skin”), specifically large sulfur bacteria (Steiner and Reitner, 2001). At ca. 560 Ma, unequivocal trace fossils prove the existence of bilaterians (see discussion of problematical trace fossil records from 1 Ga in Jensen, 2003). Dated as 580–570 Ma, the Wengan Phosphorites (Doushantuo Group, China) yielded structures that resemble metazoan embryos, but its metazoan nature has recently been doubted and reinterpreted as phosphatized, large sulfur bacteria with affinities to the *Thiomargarita* group (Bailey et al., 2007). However, possible body fossil of sponge larvae occur also, and by 550 Ma, fossil sponges (Hexactinellida) are known from the Dengying Formation (China). Of the same age is *Kimberella* (White Sea region), which is interpreted as a nonmineralized mollusk, which then marks also the first body fossils of a bilaterian metazoan. The same period

Critical Intervals in Earth History, Figure 3 Summary of evolutionary and paleobiological landmarks in the Upper Proterozoic to Middle Cambrian; mainly based on the compilations of Valentine (2002) and Marshall (2006); with further references therein. Archaeocyatha: dashed lines indicate rare or no records and link to the Upper Cambrian occurrences of Antarctica (Debrenne et al., 1984). Dating of first Cnidaria around 555 Ma after Xiao et al. (2000).

also marks the onset of enzymatic biocalcification. The first mineralized skeletons occur in the form of *Namacalathus* and *Namapoikia* in Namibia around 550 Ma, which could be coralline sponges (Grotzinger et al., 2000; Wood et al., 2002). Calcified tubes of *Cloudina* (Figures 7 and 8) show large resemblance with the deep sea vent and cold seep related *Escarpiia*, a pogonophorid worm. All three taxa occur together within thrombolithic and finely laminated microbial assemblages in the first reef-like structures in the form of small mud mounds (Figure 9).

In the Lower Cambrian (Nemakit-Daldynian), calcareous Archaeocyatha (possible Demospongia) formed the first Cyanophyta/sponge mud mounds. Concomitantly, phosphatic and calcitic microfossils or mineralized sklerites of parts of unknown organisms, the Small Shelly Fauna, SSF, appeared – partly in large abundances – worldwide. Only little later, in the Lower Tommotian, first

shells of brachiopods, mollusks, and arthropods occurred (for an overview of the biotic development prior to the Cambrian Explosion see Valentine, 2002; Xiao and Kaufman, 2007).

Ecologically, most of the Ediacaran period was considered as a peaceful “Garden of Ediacara” by McMenamin (1986), as no evidence of predation is known from this time. Instead, it appears that the biomat-related Vendobionta represented an ecologically and evolutionary very stable steady-state system without any significant innovations for over 30 Ma. Thus, the slowly increasing disparity, which we recognize close to the base of the Cambrian, resulted exclusively from speciation among the Metazoa. Even more, paleobiogeographical and facies affinities (e.g., different species of *Cloudina* occupied different habitats) were now recognizable. And, trouble in paradise became visible by small holes in *Cloudina* – the first evidence of predator–prey interaction (Hua et al., 2003).

Critical Intervals in Earth History, Figure 4 Chengjiang Biota (Lower Cambrian): Anterior parts of *Yunnanzoon lividum* with structures resembling gills or branchial arches. Although previously interpreted as a Chordata, its systematic position is still enigmatic; see also Hou et al. (2004). Scale bar: ca. 10 mm (coll. J. Reitner, GZG Göttingen).

Critical Intervals in Earth History, Figure 5 Chengjiang Biota (Lower Cambrian): The worm *Paleosolex sinensis*, a representative of the Nematophora and a very common element of the Chengjiang fauna; see also Hou et al. (2004). Scale bar: 5 mm (coll. J. Reitner, GZG Göttingen).

The increasing complexity among the Metazoa finds its expression also in progressively more complex burrow systems. While in the Middle Ediacaran sub-biomat miners created simple horizontal furrows on the sediment's surface, terminal Ediacaran burrows became three-dimensional, such as, for example, *Trichophycus pedum*, the biostratigraphical index marker for the base of the Cambrian system (ca. 542 Ma). It is specifically this trend, which was responsible for the first severe extinction among multicellular animals: approximately at the base of the

Critical Intervals in Earth History, Figure 6 Vendobionta: *Ernietta* mass occurrence in small-scale channel deposits, Namibia.

Critical Intervals in Earth History, Figure 7 First calcareous biomineralization: Thin sections of *Cloudina* from the Dridoorvlatke area, Namibia. Cross section; Scale bar: ca. 5 mm.

Cambrian, the Vendobionta decreased significantly in abundance to become completely extinct in the Lower Cambrian. Seilacher and Pflüger (1994) suggested that the progressive complexity among infaunal burrowers and burrow intensities resulted in an irreversible destruction of the microbial mats – the essential for the Vendobionta (agronomic revolution).

Possible reasons for the Cambrian Explosion

For the slow but continuous increase of disparity and diversity over ca. 60 Ma in the terminal Ediacaran and its explosive increase around 524 Ma, a number of possible triggering mechanisms are suggested, proposing changes in the abiotic, biotic, and genetic evolutionary landscapes (see, a.o., Marshall, 2006 and Levinton, 2008 for a compilation).

Changes in the abiotic evolutionary landscape (environmental changes)

- (a) *Oxygen level*: An explanation for the increasing disparity in the Ediacaran might be a second oxygenation event to a pO_2 near modern values as deduced from chromium isotopes ($\delta^{33}\text{Cr}$) around 800–542 Ma (Frei et al., 2009) or by 580 Ma (Canfield et al., 2009). Before this time, geographically widespread occurrences of black shales indicate anaerobic deep oceans: due to the aerobic continental weathering of detrital pyrite and, resulting, riverine sulfate input into the

Critical Intervals in Earth History, Figure 8 First calcareous biomineralization: Thin sections of *Cloudina* from the Dridoorrvlakte area, Namibia. Latitudinal section; Same magnification like Fig. 7.

oceans, its bacterial reduction caused deep ocean saturation of H_2S (“Canfield Ocean,” see Canfield, 1999; Figure 2). This caused a reduction of iron, copper, and molybdenum, all less soluble under the presence of hydrogen sulfide. Because these play important roles in the enzymatic metabolism of the Cyanophyta, the depletion of these elements caused malnourishment, which might have blocked evolutionary advance for more than a billion years. Only after the last episode of the Snowball Earth period (Gaskiers Glaciation), molybdenum isotopes indicate a second oxygenation event and progressively oxygenized deeper part of the oceans. This could have increased the capacity for metabolism of larger Metazoa and the evolution of the Vendobionta and first metazoans can be seen in the light of this atmospheric/oceanic change. However, the long delay between the terminal Proterozoic oxygenation event and the Cambrian Explosion of estimated 50–60 Ma makes a direct link unlikely. On the other hand, the increased O_2 amount doubtlessly acted as an indispensable prerequisite for size increase and evolution of the Metazoa.

- (b) *Global carbon cycle*: In the Vendian/Cambrian boundary interval, numerous published $\delta^{13}\text{C}$ curves show vivid fluctuations and a negative $\delta^{13}\text{C}$ peak with up to -12 per mil in the Upper Ediacaran. The observed $\delta^{13}\text{C}$ fluctuations are surely expression of heavy perturbations in the global carbon cycle and, thus, indicate environmental disturbances. There is a wealth on literature on this problematic, and variety of complex and differing explanation models exists, as illustrated by two examples: For the terminal Ediacaran negative $\delta^{13}\text{C}$ peak, Kirschvink and Raub

Critical Intervals in Earth History, Figure 9 Latest Proterozoic mud mounds, exhumed by erosion, with *Namacalathus* (sponge?), *Cloudina*, and thrombolithic microbial limestones. Swartkloof area, Namibia.

(2003) postulated methane release, resulting in a rise of global temperatures as a triggering pulse for the Cambrian Explosion, while Bristow and Kennedy (2008) suggested that the negative excursion resulted from a non-steady-state oxidation of oceanic dissolved organic carbon (DOC), resulting from a rise of atmospheric oxygen (see above).

- (c) *Ocean water chemistry*: The ocean water geochemistry changed progressively from a Proterozoic soda ocean towards a late Proterozoic halite ocean during the Ediacaran (e.g., Hardie, 2003). As seawater carbonate alkalinity triggers the possibility of Ca^{2+} extraction, the decreasing pH values progressively facilitated enzymatic CaCO_3 mineralization. Geochemical data from terminal Proterozoic (~544 Ma) and early Cambrian (~515 Ma) marine halite indicate that seawater Ca^{2+} concentrations increased approximately threefold during the early Cambrian (Brennan et al., 2004). A high Ca^{2+} and low $[\text{SO}_4]^{2-}$ composition of the early Cambrian sea water is recorded by Petrychenko et al. (2005), which then could be responsible for the sudden occurrence of organisms with strongly mineralized shells and sklerites consisting of CaCO_3 .
- (d) *Global sea-level and paleoceanography*: The terminal Ediacaran is a period of global sea-level rise, and the break-up of Rodinia from ca. 850 Ma on created a huge amount of environmentally differentiated shelf areas, which became flooded during this interval. These provided an immense potential for specialization and diversification of shelf organisms. However, from the Ediacaran through the Cambrian, there is a continuous flooding of shelf areas (Miller et al., 2005; Haq and Schutter, 2008), and there seems to be no or only little relation to the Cambrian Explosion.

Changes in genetic and developmental capacities

With the first occurrence of the Bilateria, the bilaterian development system had developed. When we accept the Ediacaran *Kimberella* as a molluscan Bilateria, then the bilaterian development system must predate the Cambrian Explosion significantly. As a small increase of genomic complexity can result in high morphological diversity, the Cambrian Explosion cannot exclusively be explained by developmental innovations (see compilation and discussion in Marshall (2006).

Changes in the biotic environment

Interactions among organisms is difficult to recognize in the fossil record. However, predator–prey relations could be reconstructed in some cases as we see traces of predation, manifested by damages in mineralized skeletons. The first record of predation is known from small holes in *Cloudina*, bioerosive evidence of predation. With the arthropod *Anomalocaris* from the Lower Cambrian (Chengjiang Biota), a first top predator occurred. This shows that predation pressure and the need to predate had well established, which opened a wide window for

any imaginable evolutionary interactions and its morphological manifestation in the form of a biological arms race.

Biomineralization

After all, the Cambrian Explosion is phenologically also an expression of increased biomineralization, why it is also a biomineralization event. We have no knowledge about diversity of any nektonic and benthic nonmineralized bilaterians before the Cambrian Explosion, because they are simply not preserved. To argue that the increase of trace fossil diversity matches that of the body fossil diversity is in a strict sense not feasible because trace fossils are expression of behavior, and it is impossible to deduce body fossil diversity from trace fossil diversity (the same type of trace fossil can be generated by several organisms of different groups).

Concluding remarks

The rise of the Metazoa and increasing bioturbation of the sea floor resulted in the extinction of the Vendobionta – the first period of multicellular animals extinction in Earth's history (if one accepts that the Vendobionta are multicellular eukaryota). The succeeding Cambrian Explosion is still difficult to interpret. Although there are a number of possible explanations for environmental and biological changes during the Lower Cambrian, none of the mechanisms alone provides sufficient argument to exclusively explain the explosive radiation of invertebrates within this short period of only ca. 10 Ma so far.

The rise of land plants

Generalities

The first multicellular marine plants are known since ca. 1.2 Ga (Butterfield et al., 1990; Figure 2), and although molecular data suggest some kind of very primitive land plants around 700 Ma (Heckman et al., 2001), it took further 230 Ma until first multicellular complex land plants (Embryophyta) occurred in the Lower(?) Middle Ordovician (Darriwillian, ca. 465 Ma). These records are phytodebris and cryptospores with uncertain affinities (Steemans and Wellman, 2004; Figure 1). In the Upper Ordovician to Lower Silurian, cryptospore diversity and abundance decreased significantly, while trilete/hilate spores became frequent, radiated, and finally, the first vascular plant remains occurred in the Silurian (Wenlock) ca. 40 Ma later (e.g., Wellman et al., 2003; Gensel, 2008). A first spectacular fossilagerstätte of advanced Embryophyta is the Lower Devonian Rhynie Chert with excellently preserved cellular structures (Figure 10), and it is possibly the best investigated case study of an early terrestrial ecosystem (see Wellman, 2004; Taylor et al., 2005; with additional references therein). Still in the Devonian, first seed plants, trees and multi-storied forests occurred. Overviews over the (early) land plant evolution can be found, a.o., in Graham et al. (2000), Gensel and Edwards (2001) or Gensel (2008).

Critical Intervals in Earth History, Figure 10 Thin section of a piece of Rhynie Chert. Well visible are the excellently preserved cellular structure of the silicified plants remains (*Aglaophyton major*). (Stem cross section ca. 3 mm). (coll. J. Reitner, GZG Göttingen).

Associated environmental changes

There can be no doubt that the occupation of land with its succeeding evolutionary evolutions over ca. 60–80 Ma represents possibly the most significant step in plant evolution since the development of the first eukaryotic plant cell. However, the progressively increasing occupation of the continents by land plants resulted also in significant changes in Paleozoic ecosystem structures and had severe impact on a number of geological processes such as weathering, the development of the atmosphere, and global carbon and hydrological cycles.

Development of land animals

The spread of land plants represented a first significant occurrence and increase of terrestrial primary productivity and, thus, the prerequisite for animal life on the continents. However, DiMichele and Hook (1992) suggested that there existed no direct positive correlation between land plant and early land animal evolution in the sense of herbivory. Instead, the biomass affected the animal food web *via* a detritus chain. The increasing complexity of terrestrial animal ecosystems can be deduced by the progressive diversification of arthropods as well as trace fossil abundance in paleosoils and continental deposits from the Ordovician on (see Retallack and Feakes, 1987; Buatois et al., 1998), and the occurrence of simple food webs are suggested by the finds of predatory arthropods already for the Silurian (Jeram et al., 1990).

Effect on continental weathering, erosion and nutrients

The evolution of plants and the occurrence of deep roots triggered the development of paleosoils, which are known since the Ordovician (see overview in Retallack, 2005). The roots favored physical weathering, and the evolution

of root symbionts such as mycorrhizae acted as a chemical weathering agents. A further pedogenic factor is the increasing amount of bioturbation, which, by its large surface and permeability, favored chemical weathering. The development of soils advanced likewise erosion and an increased continental run-off of nutrients in to the oceans (see Algeo and Scheckler, 1998).

Effect on the atmospheric composition

With the occurrence of land plants, a feedback system between atmospheric CO₂ evolution and land plants established (see Beerling and Berner, 2005). The withdrawal of CO₂ by photosynthesis and by increased weathering of Ca–Mg silicates resulted in progressive drop of atmospheric *p*CO₂ from the Silurian on (Beerling and Berner, 2005).

Concluding remarks

Although the development of continental ecosystems is much less appreciated in the literature than marine environments, the significance of the land plant evolution is enormous. Apart from the above-mentioned geological aspects, the development of continental primary productivity was the base for animal life on land and the progressive establishment of complex ecosystems as we see them today. Plants did the first step, animals followed. The shore leave of the vertebrates in the Devonian would not have been possible without the occurrence of land plants.

Extinction events

Generalities

An extinction event is the – in a geological sense – abrupt decrease of speciation, diversity, and abundance within a geologically very short time. It affects all groups of organisms at various degrees. As mentioned above, we do not consider extinction events as classical critical intervals, as we never see the extinction, or in the aftermath of extinction, the entry, of new phyla. Instead, we see something like a phylogenetic steady-state, where even after heavy extinction no evolutionary playground for complete innovations at high levels was created.

The “Big Five”

Classically, five main extinction events are distinguished in the Phanerozoic, in the literature referred to as “the Big Five.” These are (Figure 1)

1. The Upper Ordovician event with an estimated extinction of ca. 85% of the marine species and ca. 50% of marine genera (see overview in Krug and Patzkowsky, 2004 and Sheehan, 2001).
2. The Upper Devonian Kellwasser and Hangenberg events (Frasnian/Famennian boundary) with an extinction rate of ca. 20% of all animal families and 70–80% of all animal species (see overview in McGhee, 1996; Over et al., 2005; Becker and Kirchgasser, 2007).
3. The Permian–Triassic boundary (P/Tr boundary event) with an extinction of ca. 95% of the shelf biota and

65–70% of the vertebrates. Nicknamed “The Big Dying,” it was the most dramatic mass extinction in the Phanerozoic (see overview in White, 2002; Over et al., 2005; Şengör and Atayman, 2009).

4. At the Triassic–Jurassic boundary (Tr/J boundary event) with a loss of ca. 77% of all species and ca. 41% of all mesobenthic and macrobenthic genera (see overview in Tanner et al., 2004; Hesselbo et al., 2007).
5. At the Cretaceous/Tertiary boundary (K/T boundary event). This event caused extinction of ca. 65% among the species. Among the victims were so popular groups such as ammonoids and dinosaurs (see overview in Ryder et al., 1996; MacLeod et al., 1997).

Causes

There exists a flood of ideas and literature about the possible causes of mass extinctions with complex interactions and feedback mechanisms. Here, some of the popular concepts will be briefly introduced, which either focus at the trigger or the kill mechanisms.

Impact events. The trend-setting discovery was the recognition of an iridium anomaly at the K/T boundary Event by Alvarez et al. (1980), who suggested that a bolides’ impact was responsible for the end-Cretaceous extinction of dinosaurs and a great number of typical Cretaceous marine invertebrates such as ammonites, belemnites, inoceramids, and rudist bivalves. Later, tektites (impact glasses) were discovered in the boundary interval in numerous sections worldwide. Today, the Chicxulub structure on the Yucatan peninsula of Mexico (ca. 170 km diameter) is seen as the associated impact structure, although there is still some controversy about the stratigraphical fit of the extinction and the dating of the impact (Keller et al., 2007). The inferred relation between mass extinction and large impacts resulted in a search of impact evidences such as craters, spherule layers, iridium anomalies, or certain noble gases in fullerenes that correlate stratigraphically with other large extinction events. The Siljan impact structure in Sweden (diameter: ca. 55 km, age: ca. 368 Ma) was shown to correlate with the Upper Devonian Kellwasser-Events, from which also microtektites are known (Claeys et al., 1996). In the case of the Permian/Triassic boundary interval (ca. 250 Ma), the dating of the Araguinha structure of Brazil (diameter ca. 40 km, age: ca. 445.5 $\pm$ 3.5 Ma: Hammerschmidt and Engelhardt, 1995) shows good temporal accordance. For the Triassic/Jurassic boundary extinction (ca. 199.6 Ma, Gradstein et al., 2004), the Manicouagan impact structure, Quebec, Canada (diameter: ca. 100 km) was made responsible (Olsen et al., 1987). However, refined dating shows that its age is 215.5 (Ramezani et al., 2005), postdating the extinction level significantly (see Kelley, 2007 for a discussion of the problematical stratigraphical accuracy of impact – mass extinction correlation). Possible killer are believed to be direct physical effects such as shock waves, heat and fire, impact winter, succeeding warming, collapse of the food chain, or environmental acidification. However, it

appears that of the Big Five only for the K/T boundary extinction, an impact as a possible cause is still seriously discussed.

Flood basalt volcanism. Catastrophic outflow of gigantic flood basalts (continental flood basalt provinces, large igneous provinces) co-occur with the Permian/Triassic boundary event (Siberian flood basalts), the K/T boundary event (Deccan Trapps, India) and the Triassic/Jurassic boundary event (Central Atlantic Magmatic Province, CAMP). They are believed to have triggered mass extinction by the production of large amounts of CO₂ (e.g., Fraiser and Bottjer, 2007) and SO₂ either *via* climate changes resulting in the either warming or cooling or *via* feedback loops causing oceanic anoxia or gas hydrate release (see Wignall, 2001 for a summary and Kelley, 2007).

Anoxic events. Oceanic anoxic events, indicated by the occurrence of laminated marine black shales, are common phenomena in Earth’s history and were made responsible for some extinction events such as the Kellwasser events (late Devonian), the P/Tr and Tr/J boundary events and some subordinate extinctions such as the Cenomanian/Turonian boundary event. For the P/Tr boundary event, even photic zone anoxia was suggested, caused by release of deep-sea originated hydrogen sulfide to the surface (Kump et al., 2005; Meyer et al., 2008; the superanoxic event of Grice et al., 2004). However, oceanic anoxia alone fails to explain the extinction of land plants and animals.

H₂S release into the atmosphere. In the cause of massive oceanic anoxia, hydrogen sulfide is believed to have been released into the atmosphere. H₂S toxicity and hypercapnia are suggested as possible killing mechanisms (Meyer et al., 2008).

Explosive methane release. The release of methane is believed to be an associated process of catastrophic global warming in the context of catastrophic volcanisms and greenhouse gas emission (s.o). However, Ryskin (2003) suggested in the case of the P/Tr boundary event that the explosive release of methane by the collapse and instability of gas hydrates brought anoxic deep waters with hydrogen sulfide to the surface, causing mass extinction of the shelf biota.

Glaciations, warming, cooling. The succession of a severe cooling, followed by warming was made responsible for the end-Ordovician extinction. The model proposes an equator-shift of boreal taxa and extinction of warm-water fauna. *Vice versa*, in the next step, warming caused a poleward-shift of warm waters and extinction among cold-water faunas. In addition, the associated glacioeustatic sea-level low diminished shelf areas and caused stress on the shelf biota (see discussion in Hallam and Wignall, 1997 and an ecological approach in Twitchett, 2006). The reasons for Phanerozoic glaciations are not always clear to elaborate; in the case of the late Ordovician glaciation, withdraw of atmospheric CO₂ as a result of increased continental weathering due to volcanism-induced atmospheric SO₂ emission is suggested (Young et al., 2009).

Sea-level changes. Sea-level changes are observed to co-occur with mass extinctions and are suggested to be a possible triggering mechanism. However, while for the Ordovician a glacio-eustatic sea-level low is suggested to be responsible by some authors (see above), strong transgression with the establishment of anoxia is suggested by others (e.g., Kellwasser Event: Bond and Wignall, 2008). There is no universal model for how sea-level changes effects extinction. A more general discussion on that topic is given by Peters (2008).

Gamma ray burst. For the end-Ordovician extinction, a gamma ray burst was suggested by Melott et al. (2004). It resulted in a depletion of the ozone layer and increased UV radiation, which is believed to be lethal to numerous groups of surface-dwelling organisms and the phytoplankton. Furthermore, a gamma ray burst can produce atmospheric opaque nitrogen dioxide, resulting in an increased back-scatter of sunlight, which provides a feasible mechanism for a global cooling.

Urease dead zones. Wooldbridge (2008) suggested that the pH dependency of the enzyme urease might be the explanation for the end-Devonian, the P/Tr, the Tr/J and the K/T boundary events. Urease catalyzes the hydrolysis of urea into ammonia and CO₂. It enables organisms to access urea as a source for metabolism, and it is a very important enzyme for biomineralization of carbonate and nitrogen accessibility during early stages in ontogenetic development. It is equally important in numerous plants, bacteria, fungi, and invertebrates, but not the vertebrates. At pH 7.9, the enzyme becomes inactivate, forming a dead zone between some pH optima. Thus, any sudden or long-term changes in the CO₂ concentration (e.g., flood basalt volcanisms), and, resulting, fluctuations of pH values crossing the magic 7.9 boundary, might potentially be phases of extinction.

Halogenated gas emission. Based on recent investigations in evaporitic environments, Weissflog et al. (2008) suggested that during evaporation in the central European Zechstein basin (South Permian Basin; Upper Permian) bacterially-derived, toxic volatile halogenated hydrocarbons (HCC; e.g., chloroform, trichloroethylene, tetrachlorethylene) emitted into the atmosphere. They damaged the ozone layer and – by increased UV radiation – the Permian biosphere. Likewise, the phytotoxicologic effect of the HCC provided a direct kill mechanism for Permian biota.

Concluding remarks

When reviewing the literature it becomes clear that for the “Big Five” no single cause mechanism is accepted (Elewa, 2008). A number of possible “killer” are discussed for each period of mass extinction, and in the case of the Permian/Triassic event, 6 potential suspects (cooling, warming, anoxia, volcanism, impact, methane release) were summarized by White (2002). Even the K/T boundary event is still split into two groups, one favoring an impact, the other flood basalt volcanism.

Overviews on the possible triggering mechanisms, with explanations of the complex feedback interrelations based on case studies can be found, for example, in Ryder et al. (1996), Wignall (2001), Taylor (2004), Hallam (2005) and Twitchett (2006), and some data on the biotic response in the context of mass extinctions can be found in Hart (1996) or Hallam and Wignall (1997). The still large number of newly published papers and debates show that extinction is still a hot topic, and while some theories will turn out to be persistent, other will be volatile.

Definition

Cyanobacteria are a large and morphologically rather diverse group of photoautotrophic prokaryotes and are classified as a monophyletic phylum within Domain Bacteria. Cyanobacteria share oxygenic photosynthesis with the eukaryotic algae. Cyanobacteria belong to the oldest organisms on earth. Their broad environmental tolerance range makes cyanobacteria well suited to live in habitats of extreme and fluctuating conditions where they can outcompete eukaryotic algae.

Many cyanobacteria have large cells like the eukaryotic algae with which they share the same life-style: Consequently, they are often treated as prokaryotic algae or, formerly, blue-green algae. Some cyanobacteria even form macroscopic colonies from the size of a few millimeters to up to 30 cm (Dodds and Castenholz, 1988). Cyanobacteria occur in a broad variety of forms, from solitary unicells over colony-forming and undifferentiated filamentous types to more complex forms that even display the hallmarks of multicellularity. Photosynthetic cyanobacteria produced earth's first oxygen atmosphere, which fostered the rise of eukaryotes. In addition, ancient cyanobacteria produced massive undersea carbonate deposits, thereby reducing atmospheric carbon dioxide levels and influencing global climate. The first plastids arose from cyanobacteria through a process called primary endosymbiosis (McFadden, 2001; Keeling, 2004; Palmer, 2003; Reyes-Prieto et al., 2007). Modern cyanobacteria are recognized for their ability to occupy diverse aquatic and terrestrial habitats, cyanobacteria produce organic compounds used by other organisms, and they stabilize sediments and soils. Nitrogen-fixing cyanobacteria increase soil and water fertility and foster the growth of certain plants and fungi in symbiotic associations. There is strong evidence that cyanobacteria are the oldest microorganisms performing oxygenic photosynthesis, dating back to about 2.45 billion years (Rasmussen and Willemotte, 2008) and with an evolutionary history stretching over at least 1.5 and possibly 2.7 billion years (Blank, 2004). Cyanobacteria are able to live in some of the most extreme habitats on earth (e.g., Seckbach, 2007 for an overview). The broad environmental tolerance range of cyanobacteria in extreme habitats is in contrast to most other prokaryotic and eukaryotic organisms from extreme environments that occur only within a small window of almost constant conditions. From an evolutionary point of view, it appears that cyanobacteria which are

among the oldest organisms on earth may have been forced by the “modern” eukaryotes to withdraw themselves into habitats of extreme and fluctuating conditions (Whitton, 1992; Bhattacharya et al., 1999).

Cell structure

Unlike most groups of prokaryotes, there is substantial morphological and life history variation within the cyanobacteria (Hayes et al., 2007). Although some cyanobacteria occur as solitary unicells, in most species the cells adhere at each other to form at least pairs of cells (representing the products of a recent cell division, *Synechococcus* Figure 1a) or group of cells are held together to form colonies (e.g., in *Myxosarcina*, Figure 1b). Very common growth forms are filaments (trichomes) where the cells are joined end to end through regular divisions into one plane (Figure 1c–g). Such filaments can be even joined into bundles or can be branched (true-branched, Figure 1b or false-branched, Figure 1d). Many filamentous cyanobacteria produce specialized cells known as heterocytes (formerly heterocysts; Figure 1d and g) that function in nitrogen fixation. Such cyanobacteria are usually capable to produce specialized cells for dormancy, known as akinetes, under adverse environmental conditions. Some filamentous cyanobacteria are capable of gliding, a slow uniform motion on a solid substrate. The gliding occurs by an interaction of slime secretion and certain proteinaceous fibers (Hoiczyk, 2000). Cyanobacteria lack sexual reproduction, but gene exchange may be realized through viral transduction by specialized cyanophages (Coleman et al., 2006). The only mode of reproduction is by cell division (binary fission, resulting in two equal-sized cells) or simply by fragmentation of a colony. In unicellular cyanobacteria, baeocytes (endospores) are formed by the division of the cytoplasm several times and in different planes whereby the mother does not increase in size. Filamentous cyanobacteria form hormogonia (Figure 1e), which are short filaments resulting from a breakup of a longer filament, promoted by the controlled death or collapse of certain cells. Hormogonia exhibit gliding motility for several hours, are positively phototactic and lack heterocytes. Light is absorbed by thylakoids, photosynthetic membranes, which are arranged concentrically at the cell periphery, not stacked and not connected to the plasma membrane. They contain the chlorophylls *a* and *d*, in some cyanobacteria also chlorophyll *b*, as well as carotenoids and phycobilins as accessory pigments to capture light energy and convey it to the photosynthetic reaction centers located inside the thylakoid membranes. Phycobilins are blue or red water-soluble pigments and are present in large amounts. They are bound to proteins that form up hemispherical phycobilisomes which occur on the outer thylakoid surfaces. Several particles in the cytoplasm of cyanobacteria may represent storage products, that is, cyanophycin (a polymer of the nitrogen-rich amino acids asparagine and arginine), cyanophycan starch

(a polyglucan), and polyphosphate. In addition, lipid droplets, carboxysomes (polygonal aggregations of *Rubisco*, the key enzyme in CO₂ fixation), and gas vesicles may be present in the cytoplasm. Gas vesicles (assemblies of hollow, pointed cylinders, but not delimited by membranes) occur frequently in aquatic cyanobacteria and enable them for buoyancy and to confer vertical mobility in the water column. The cell wall of cyanobacteria is basically the same as for Gram-negative bacteria, that is, a thin peptidoglycan layer (a polymer composed of sugar derivatives and amino acids) is outside of the cell membrane (cytoplasm membrane). Outside of the peptidoglycan layer is a space surrounded by another membrane, termed outer membrane. A very characteristic feature of cyanobacteria is that they usually are surrounded by a mucilaginous sheath (extracellular polymeric substances [EPS], see entry “*Extracellular Polymeric Substances (EPS)*”), mostly composed of polysaccharides, which protects the cells from drying and enables them to attach to substrates.

Ecology

Cyanobacteria are widely distributed in aquatic and terrestrial environments, including such extreme habitats as hot springs, deserts, and polar regions (Whitton and Potts, 2000). Many cyanobacteria are diazotrophic, that is, they can fix atmospheric molecular nitrogen gas (N₂) into ammonia which is then further assimilated into amino acids and proteins. Nitrogen fixation is an inducible process and is exceptionally energy demanding. The environmental levels of ammonium or nitrate regulate it and it can only be performed if sufficient ATP (produced by photosynthesis) is available. The key enzyme of nitrogen fixation is nitrogenase, which is irreversibly inhibited by oxygen and, therefore, nitrogen can only be fixed under anaerobic conditions. Cyanobacteria that produce heterocytes are capable to fix nitrogen even in aerobic habitats, because several processes within the heterocytes (e.g., intracellular respiration) consume oxygen and the heterocytes’ thick cell walls reduce diffusion of oxygen into the cells. Cyanobacteria without heterocytes may fix nitrogen in the dark. Bloom-forming filamentous cyanobacteria devoid of heterocytes are responsible for fixing one-quarter of the total nitrogen in the oceans (Bergman and Carpenter, 1991). These cyanobacteria fix nitrogen in randomly distributed vegetative cells adjacent to each other within the filaments. Here and inside the colonies, the filaments may be depleted from oxygen. In addition, these species occur in tropical seas that are relatively low in dissolved oxygen. The ability to fix molecular nitrogen makes cyanobacteria attractive as symbionts for many eukaryotes because eukaryotes are not able to fix nitrogen. Very common occurrences of nitrogen-fixing cyanobacteria as extracellular symbionts are lichens, that is, symbioses with certain fungi (Friedl and Büdel, 2008, see entries “*Symbiosis*” and “*Fungi and Lichens*”). In the marine environment, cyanobacterial symbioses are known

Cyanobacteria, Figure 1 Different cyanobacterial morphotypes from pure culture. Figure a, d–g show strains recovered from tufa stromatolite biofilms of hardwater creeks: (a) coccoid unicellular *Synechococcus* sp. The cells adhere at each other to form at pairs representing the products of a recent cell division (Photograph taken by A. Hodačova); (b) *Myxosarcina* sp. (strain SAG 30.84) with adhering groups of cells forming irregular colonies (Photograph taken by A. Hodačova); (c) filamentous, true-branched *Stigonema* sp. (strain SAG 49.90) (Photograph taken by A. Hodačova); (d) filamentous, false-branched *Tolypothrix* sp.; (e) thick unbranched filaments of *Lyngbya* sp. forming hormogonia; (f) thin unbranched filaments of *Pseudanabaena* sp. which are fragmenting (Photograph taken by A. Hodačova); (g) filamentous *Nostoc* sp. forming gelatinous colonies. Insert, filament with a heterocyte located within the filament (intercalary) (Photographs taken by A. Hodačova); (h) Fluorescence in situ hybridization using an oligonucleotide probe specific for bacteria at a cryosection of the top of a tufa-forming biofilm. The red filaments represent cyanobacteria (*Phormidium* sp.). Cyanobacterial autofluorescence is shown in red and calcite in white (Photograph taken by G. Arp, printed with permission of the publisher). Scale bar, 20 μm .

with sponges, ascidians (sea squirts), and echiuroid worms in the benthos and diatoms, as well as dinoflagellates in the plankton. These symbioses can be significant in terms of the biogeochemistry of coastal and open-ocean areas (Carpenter, 2002). Planktonic diatom–cyanobacteria symbioses play a significant role in the ecology and biogeochemistry of the surface ocean (see entry *Algae, Eukaryotic*). Symbiotic associations with cyanobacteria are also known from plants. In the water fern *Azolla* and cycads where filamentous cyanobacteria with heterocytes occur within certain cavities inside the leaf and intercellular spaces inside the root, respectively (Lee, 2008; Graham et al., 2009). N₂-fixing cyanobacteria are common in waterlogged rice fields and the importance of these naturally occurring prokaryotes in the nitrogen economy of rice cultivation has long been known (Whitton, 2000). To support the demand for nitrogen in rice cultivation, input of chemical N fertilizers is a prerequisite, but the inoculation with free-living N₂-fixing cyanobacteria as biofertilizers has been shown to increase growth and crop yield of rice. An example for intracellular associations involving cyanobacteria can be found in certain diatoms (see entry *Diatoms*).

The cyanobacteria metabolic activities make quantitatively important contributions to the carbon, nitrogen, sulfur, and other biogeochemical cycles (Hayes et al., 2007). There is an enormous variety of habitats where cyanobacteria play important roles, but to discuss this comprehensively is beyond the scope of this article. Therefore, we confine the discussion of cyanobacteria ecology just to a few selected examples. Other examples may be equally intriguing and important. In the littoral zone of marine environments, cyanobacteria form thin adhering films on porous or soft granular rocks within the spray zone. Cyanobacteria of the littoral zone make a significant contribution to the productivity of rocky shores (Lee, 2008). In the open-ocean minute unicellular cyanobacteria (less than 2 µm in diameter) may occur in high concentrations due to their adaptation to low light and effective nutrient uptake kinetics. Here, cyanobacteria represent the major organisms of the picophytoplankton (Ferris and Palenik, 1998) that dominates biomass and production of these oligotrophic habitats. Massive development of nitrogen-fixing filamentous cyanobacteria occur in certain tropical waters and the large surface area produced by the cyanobacterial filaments forms miniature ecosystems (Carpenter et al., 1992; Lee, 2008). Also in freshwaters blooms of cyanobacteria are common. Bloom-forming cyanobacteria often release significant toxic substances, termed cyanotoxins, with physiologically two types, neurotoxins and hepatotoxins (e.g., Codd et al., 1999). Cyanotoxins may function as anti-herbivore chemicals and can inhibit the growth of other algae. Cyanobacteria are also well known from hot acidic springs throughout the world (e.g., Ward and Castenholz, 2000). Many physiological properties that make the cyanobacteria capable to adapt to a large variety of extreme and environmental conditions may also indicate

their long evolutionary history. Many cyanobacteria are able to tolerate low oxygen conditions and even free sulfide at levels much higher than those tolerated by most eukaryotic algae. Many terrestrial cyanobacteria can tolerate high UVB and -C radiations, which may also be reminiscent of an adaption to early earth's conditions. Some cyanobacteria can even confer anoxygenic photosynthesis where H₂S is utilized as an electron donor. Cyanobacteria are also very successful primary colonizers in terrestrial habitats due to their tolerance of desiccation and to water stress. In biological soil crusts of semideserts, for example, cyanobacteria play a key role in maintaining the stability of the surface (e.g., Büdel et al., 2009). As they bind sand and soil particles, cyanobacteria prevent erosion. They help to maintain moisture in the soil and contribute nitrogen to it through nitrogen fixation. That may even assist higher plant growth by supplying growth substances (Lee, 2008). The cyanobacterial genus *Arthrospira* (formerly *Spirulina*) is used as human food supplement; the *Spirulina* industry is of increasing economic importance. Large filamentous colonies of *Nostoc* are used in China as “hair vegetable” (Facai).

Many species of cyanobacteria have calcium carbonate in the enveloping mucilage of the cells; crystals of calcite may also be trapped in the mucilage excreted by the cells (see entry *Calcite Precipitation, Microbially Induced*). In the marine environment, trapping and binding of the sediments as well as carbonate precipitation by cyanobacteria led to the formation of stromatolites (see entries *Microbialites, Modern*, and *Microbialites, Stromatolites, and Thrombolites*). The production of laminae in the stromatolites depends on fluctuations ultimately derived from movements of the earth, sun, and moon, and requires rhythmicity such as daily photosynthetic cycle of the organisms in the stromatolites. Up to 2,000 million years ago, there were no grazers and boring organisms and, therefore, stromatolites grew uncontested. The occurrence and size of stromatolites declined dramatically after the evolution of grazing and boring organisms. Today stromatolites grow only in warm hypersaline waters inhospitable to grazers and borers (e.g., Shark Bay, Australia). Extant cyanobacteria do not calcify in open-ocean sea water because this water is normally not supersaturated sufficiently with calcium carbonate to allow calcification (Riding, 2000; see entry *Calcified Cyanobacteria*). However, even in extant freshwaters, calcification processes somehow similar to the stromatolite formation in marine environments occur, for example, in tufa-forming biofilms of karstwater streams (Arp et al., 2010). Epilithic cyanobacterial species may enhance calcium carbonate deposition, either by trapping particles or by contributing to communities where calcite and aragonite (in freshwaters) or other carbonates are precipitated. Endolithic species mainly occur in soft and porous limestone (Figure 1h) where they grow actively into the limestone at sites where removal of surface material occurs (Pentecost and Whitton,

2000; see entry *Endoliths*). Whether the cell surface polymers or the degradation of cyanobacterial sheath by bacterial metabolism promote the calcification is still unclear. The calcification seems to be a side effect of the cyanobacteria metabolism related to the alkalization of the surroundings during photosynthesis (Verrecchia et al., 1995). The living cyanobacteria try to limit the mineralization of the surface of their cells by some means. Nevertheless, when the calcification in cyanobacteria occurs, it is connected with their mucilaginous sheath. However, significant influence of cyanobacterial photosynthesis in the regulation of tufa-forming processes has been found recently (Bisset, 2008a, b; Shiraishi et al., 2008).

Fossil history and classification

Fossil evidence indicates that major lineages of cyanobacteria had originated 2.3–2.45 billion years ago (Eigenbrode and Freeman, 2006; Tomitani et al., 2006; Graham et al., 2009), well before the establishment of eukaryotes 1.5 billion years ago (Javaux et al., 2001). Even older fossils resembling cyanobacteria have been found in ancient stromatolites (e.g., Schopf, 2006) and geochemical evidence may also indicate an even earlier origin of cyanobacteria, but this is not left undisputed. Collectively, the available data suggest that oxygenic photosynthesis arose sometime between 3.4 and 2.3 billion years ago (Allan and Martin, 2007). For classification of the cyanobacteria, more recently a combination of phenotypic and genotypic characters has been used (Castenholz, 2001). The fact that cyanobacteria have an algal way of life – cyanobacteria “usually behave like algae” (Wilmotte, 1994) – led to treat them as plants under the botanical code of nomenclature until the late 1970s (e.g., Anagnostidis and Komárek, 1985). However, as cyanobacteria are essentially prokaryotes, their treatment under the bacteriological code of nomenclature seems more appropriate (e.g., Castenholz, 2001). For a review of the difficulties of cyanobacteria classification, see Hayes et al. (2007). Based on the most recent broad-based description of cyanobacterial taxonomy (Castenholz, 2001), cyanobacteria are classified into five subsections (Subsections I–V) which correspond to the five orders Chroococcales, Pleurocapsales, Oscillatoriales, Nostocales, and Stigonematales which have been erected under the botanical code of nomenclature. Some of the groups described by this current classification scheme are known to be polyphyletic in molecular phylogenies (for reviews see, e.g., Hayes et al., 2007). This shows that taxonomy of cyanobacteria is still in a state of flux. Still more work using multiple gene analyses as well as correction of misidentified strains in DNA sequence databases and culture collections is required to achieve progress toward a more robust taxonomy of the cyanobacteria.

Summary

Cyanobacteria form a large and morphological diverse group of photoautotrophic Gram-negative bacteria. Many cyanobacteria have large cells like the eukaryotic algae with which they share oxygenic photosynthesis. Cyanobacteria occur in a broad variety of forms, from solitary unicells over colony forming and undifferentiated filamentous types to more complex forms that even display the hallmarks of multicellularity. There is strong evidence that cyanobacteria are the oldest microorganisms performing oxygenic photosynthesis, dating back to about 2.45 billion years. Cyanobacteria exhibit a broad environmental tolerance range, which makes them well adapted to live under extreme and fluctuating conditions. From an evolutionary point of view, it appears that cyanobacteria may have been forced by the “modern” eukaryotes to withdraw themselves into such habitats. Modern cyanobacteria are recognized for their ability to occupy diverse aquatic and terrestrial habitats, cyanobacteria produce organic compounds used by other organisms, and they stabilize sediments and soils. Many cyanobacteria can fix atmospheric molecular nitrogen gas (N₂) into ammonia which is then further assimilated into amino acids and proteins. Nitrogen-fixing cyanobacteria increase soil and water fertility and are particularly attractive as symbionts, for example, to form lichens with fungi or being endosymbionts in plants, some metazoa, dinoflagellates and diatoms. The cyanobacteria metabolic activities make quantitatively important contributions to the carbon, nitrogen, sulfur, and other biogeochemical cycles.

Carbonate minerals

Definition

Carbonates. The term carbonates comprises solid phases such as minerals and amorphous substances, which basically consist of cations and triangular carbonate groups.

Introduction

The most common carbonate minerals in natural surroundings are calcite (CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$). These minerals comprise about 90 wt.% of carbonates within the Earth's crust and 10–15 wt.% of sedimentary rocks. The proportion of dolomite to calcite increases with decreasing geological age, representing the potential for transformation of calcium carbonate to dolomite at elevated temperature and high molar Mg^{2+} to Ca^{2+} ratio during geological history. Additional carbonate

minerals are numerous, but occur in rather special natural surroundings.

The occurrence and formation of carbonate minerals is mostly related to the precipitation from aqueous solutions and to a lesser extent to the crystallization from carbonate melts. In aquatic systems carbonate formation may be inorganically or biogenically induced (e.g., Morse and Mackenzie, 1990; Dove et al., 2003; Morse et al., 2007). Inorganic precipitation occurs from supersaturated solutions to form evaporites in marine and terrestrial environments, ooids in shallow water, saline lake deposits, speleothems in caves, sinter from spring water, hydrothermal ores, etc. Biogenic precipitation is mostly related to carbonates as skeletal parts and in tissues of marine and non-marine organisms such as foraminifera, coccoliths, corals, bivalves, and prokaryotes. The main mass proportion of carbonates is built from biogenic activity, whereas less arises from inorganic origin.

Once carbonate particles are formed, sedimentation may yield shelf deposits of carbonate sand or mud, deep sea ooze, or mud in lakes. Compaction, cementation, and diagenetic reactions result in lithification to limestone or calcareous marl and sandstone. Under elevated temperatures and pressures, the primary limestone may be transformed to, for example, dolomite rocks or marble.

Crystal structure and chemical composition

The basic units of carbonate minerals are cations and the triangular carbonate groups (CO_3^{2-}). The crystal structure of carbonate minerals is strongly related to the ionic radius of the cation versus the oxygen ion (e.g., Reeder, 1990). As the Ca:O ionic radius ratio in CaCO_3 is close to the upper limit for 6-coordination, CaCO_3 can occur in 6- and 9-coordination of Ca to O yielding calcite and aragonite, respectively. Accordingly, anhydrous carbonate minerals of smaller and larger cations compared to Ca^{2+} crystallize isostructurally to calcite and aragonite, respectively: (1) In the *calcite type* (trigonal carbonates), the carbonate group lies in planes at right angles to the threefold *c*-axis and the metal ions in alternate planes with a sixfold coordination of metal ions to oxygen ions (Figure 1). Metal ions of anhydrous carbonates of the *calcite type* are, e.g., Fe^{2+} , Mg^{2+} , Mn^{2+} , Cd^{2+} , and Zn^{2+} (small cations; see minerals in Table 1). (2) In the *aragonite type* (orthorhombic carbonates), a ninefold coordination of the cation to oxygen ions exists. Respective metal ions of anhydrous carbonates are, e.g., Ba^{2+} , Sr^{2+} , and Pb^{2+} as well as rare earth elements such as Sm, Eu, and Yb (large cations; Table 1).

Beside calcite and aragonite, the third CaCO_3 polymorph vaterite (hexagonal; see Figure 2) and amorphous calcium carbonate phases (ACC) can occur. Hydrus CaCO_3 minerals comprise amorphous $\text{CaCO}_3 \cdot \text{H}_2\text{O}$, monohydrocalciumcarbonate ($\text{CaCO}_3 \cdot \text{H}_2\text{O}$), and ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$). In analogy to calcium, a set of hydrus magnesium carbonates appears: Nesquehonite ($\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$), landsfordite ($\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$), and hydromagnesite ($\text{Mg}_5(\text{OH})_2(\text{CO}_3)_4 \cdot 4\text{H}_2\text{O}$).

Carbonates, Table 1 Densities and cation radii, and solubility products ($pK_S = -\log(K_S)$ at 25°C and 1 atm) of common carbonate minerals

Mineral	Formula	Density (g cm ⁻³)	Cation radius (pm)	pK_S
<i>Trigonal</i>				
Calcite	CaCO ₃	2.71	100	8.48
Siderite	FeCO ₃	3.80	78	11.03
Magnesite	MgCO ₃	2.96	72	8.10
Rhodocrosite	MnCO ₃	3.13	83	10.50
Otavite	CdCO ₃	4.26	95	12.10
Smithonite	ZnCO ₃	4.40	74	10.00
Dolomite	CaMg(CO ₃) ₂	2.87	-	17.09
Monohydrocalcite	CaCO ₃ ·H ₂ O	2.43	100	7.15
<i>Orthorhombic</i>				
Aragonite	CaCO ₃	2.93	118	8.34
Witherite	BaCO ₃	4.43	147	8.56
Strontianite	SrCO ₃	3.70	131	9.27
Cerussite	PbCO ₃	6.60	135	13.13
<i>Hexagonal</i>				
Vaterite	CaCO ₃	2.54	100	7.91
<i>Monoclinic</i>				
Ikaite	CaCO ₃ ·6H ₂ O	1.77	100	6.62
<i>Amorphous</i>				
Amorphous calcium carbonate (ACC)	CaCO ₃	-	100	6.40

Ordered double carbonate minerals are dolomite, ankerite (CaFe(CO₃)₂), kutnahorite (CaMn(CO₃)₂), huntite (Mg₃Ca(CO₃)₄), and shortite (Na₂Ca₂(CO₃)₃). In the structure of dolomite, distinct Mg²⁺ and Ca²⁺ layers alternate with CO₃²⁻ layers, whereas in the disordered protodolomite (MgCa(CO₃)₂) Mg²⁺ and Ca²⁺ are randomly distributed in the cation layer, as in Mg calcite. Carbonate minerals may contain hydroxide ions, like the copper carbonates malachite (Cu₂(OH)₂CO₃) and azurite (Cu₃(OH)₂(CO₃)₂), where the respective formation is sensitive to the CO₂ partial pressure. Typical alkali carbonate minerals are natron (Na₂CO₃·10H₂O), nahcolite

(NaHCO₃), trona (Na₃(CO₃)(HCO₃)·2H₂O), and kalicinite (KHCO₃).

Solubility and stability

The solubility of carbonate minerals is expressed by the solubility product, $K_S = (Me^{2+}) \cdot (CO_3^{2-})$ for divalent cations. Parentheses denote the activities of aqueous species at thermodynamic equilibrium. In aqueous environments the stability of minerals to each other is given by the individual values of the solubility product. At standard condition, aragonite and vaterite are more soluble than calcite (lowest K_S -value for calcite in Table 1). Accordingly, calcite is the thermodynamically stable CaCO₃ polymorph. At higher pressure, the more dense phase aragonite is the stable polymorph, although aragonite has a larger cation site due to 9-coordination of Ca to O.

Elevated temperatures cause a decrease of carbonate mineral solubility. Most reliable values of solubility products as a function of temperature are obtained by the empirical equation as compiled by Nordstrom et al. (1990). High pressure favors the dissolution of carbonate minerals as observed in seawater below ≈ 3 –5 km depths, the so-called carbonate compensation depth (CCD, e.g., Morse and Mackenzie, 1990). Deep-sea sediments below the CCD are free of calcite and aragonite.

At elevated pH in alkaline solutions, precipitation of carbonate minerals may occur due to high [CO₃²⁻] to [DIC] ratios ([]: molar concentration, DIC: dissolved inorganic carbon). Components of DIC comprise CO_{2(aq)}, H₂CO₃, HCO₃⁻, and CO₃²⁻, where CO_{2(aq)} is dominant over H₂CO₃ by a factor of 1,000 (see Usdowski, 1982). In acidic solutions the dissolution of carbonates is favored by a high H₂CO₃* content ([H₂CO₃*] = [CO_{2(aq)}] + [H₂CO₃]) and low [CO₃²⁻] to [DIC] ratios.

High ionic solute content generally results in high-dissolution capacities due to a decrease of ion activities versus the concentrations of total dissolved ions. Accordingly, calcite is more soluble in seawater than in freshwater. Seawater is slightly supersaturated with respect to calcite. Supersaturation means that the present ion activity product of the calcium and carbonate ion, $IAP = (Ca^{2+}) \cdot (CO_3^{2-})$, exceeds the K_S value for calcite (saturation degree: $\Omega = IAP/K_S > 1$), and precipitation of calcite may occur. In terrestrial solutions, like drip water in caves and spring water in karst areas, supersaturation with respect to carbonate minerals and sinter formation are mostly related to the degassing of CO₂, which results in an increase of pH.

Precipitation and dissolution

Several carbonate minerals such as calcite, witherite, and strontianite can be easily precipitated from aqueous solutions, whereas others, such as dolomite, are not easily precipitated. In the classical experimental study by Plummer et al. (1978), expressions for the dissolution and precipitation kinetics of calcite are given. Since the Plummer et al. study, various approaches have been used to model the

Carbonates, Figure 2 SEM images of inorganically induced CaCO_3 precipitates with typical shapes. (a) Rhombohedral calcite crystals associated with hexagonal plates of vaterite (CaCl_2 solution without magnesium; 30°C ; pH 9.0). (b) Small aragonite needles (CaCl_2 solution at a molar Mg^{2+} to Ca^{2+} ratio of 2; 20°C ; pH 9.0).

general relationships. Calcite dissolution kinetics is described by empirical rate expressions depending on the reaction rate constant, the reactive surface area, the volume of the solution, and the supersaturation state. More recently, Arakaki and Mucci (1995) interpreted the dissolution of calcite based on the surface complexation theory.

In natural environments, the observed precipitation and dissolution rates (R in $\text{mol m}^{-2} \text{s}^{-1}$) often disagree with the rates estimated from experimental approaches. This may be caused by an incorrect estimation of the reactive mineral surface. Lower rates in natural surroundings may also be due to inhibition by foreign ions or organic matter (e.g., Zaihua et al., 1995).

Gutjahr et al. (1996) showed that in addition to anions like phosphate, the occurrence of divalent ions such as Mg^{2+} , Fe^{2+} , Sr^{2+} , and Ba^{2+} significantly decreases the precipitation rates of calcite. In seawater, the transformation into the more stable phases is hindered by the high Mg^{2+} content. Thus, aragonite and high-Mg calcite are often found in marine sediments, although they are metastable against calcite and low-Mg calcite, respectively (Berner, 1966).

A main aspect of inhibition of carbonate precipitation in natural environments (e.g., biomineralization) and applied systems (e.g., scale formation) is the presence of dissolved organic matter, such as organic acids (e.g., Mann, 2001). For instance, polyaspartic acid can systematically and significantly modify the morphology and growth kinetics of calcite.

Isomorphic substitution

In natural systems, carbonate minerals are generally not pure substances. Impurities can be caused by isomorphic substitution of a host ion by foreign ions in a given crystal lattice. Isomorphic substitution of divalent cations in carbonate minerals depends on the cation radius, which accounts for the crystal structure and the solubility of carbonate minerals. Isomorphic substitution may result

in solid solution formation, as in the irregular but unsymmetrical SrCO_3 – CaCO_3 (aragonite type) solid solution.

Mechanisms of co-precipitation of foreign elements into carbonate minerals are complex and equilibrium thermodynamics may not be appropriate for dealing with many low-temperature reactions. On the other hand, trace element substitution in carbonate minerals can provide information about the environment conditions during formation.

The literature dealing with incorporation of trace elements into carbonate minerals is voluminous, especially with respect to the most abundant calcium and magnesium carbonates. As both the anhydrous magnesium and calcium carbonate crystallize in the *calcite type*, natural skeletal calcite can include up to about 25 mol% MgCO_3 to form so-called Mg calcite, which is isostructural with calcite. Low- and high-Mg calcites are defined by a limit of 4 mol% MgCO_3 with high-Mg calcite being less stable than low-Mg calcite. Only traces of magnesium are incorporated into aragonite as the cation sites are larger due to 9-coordination of Ca to O. Consequently, the larger Sr^{2+} ion is readily incorporated into aragonite, and less Sr^{2+} substitution occurs in calcite.

In the case of a solid CaCO_3 phase, a foreign element is incorporated into the crystal according to the overall expression

The related distribution coefficient is defined by the mole fractions X_{MeCO_3} and X_{CaCO_3} in the solid CaCO_3 and the molar Me^{2+} to Ca^{2+} ratio of the aqueous solution according to $D_{\text{Me}} = (X_{\text{MeCO}_3}/X_{\text{CaCO}_3})/([\text{Me}^{2+}]/[\text{Ca}^{2+}])$. The values of the experimental distribution coefficients for trace elements in carbonate minerals show a systematic behavior, but one that is different from that proposed by a thermodynamic equilibrium approach (e.g., Rimstidt et al., 1998; Lea, 2004; Boettcher and Dietzel, 2010).

The distribution coefficient of Mg^{2+} between calcite and aqueous solution is less than unity ($D_{\text{Mg}} \approx 0.02$ at 25°C). The higher the temperature, the more Mg^{2+} is incorporated into the calcite lattice (e.g., Oomori et al., 1987). In contrast, the distribution coefficients of Sr^{2+} in aragonite is larger than unity, and an increase in temperature results in less incorporation of Sr^{2+} into aragonite (Dietzel et al., 2004). Tesoriero and Pankow (1996) clearly showed that the incorporation of divalent cations into inorganically precipitated calcite is a function of precipitation rate. At low rates, a constant value of the distribution coefficient is reached representing thermodynamic equilibrium. Besides temperature and precipitation rates, the apparent D_{Me} values depend also on the concentrations of additional foreign ions via competitive substitution, the ionic strength of the solution, and the differential partitioning of the foreign cation on nonequivalent crystallographic faces of the carbonate mineral.

Trace element incorporation into carbonate minerals is widely used to estimate conditions of formation. For instance, Mg^{2+} to Ca^{2+} and Sr^{2+} to Ca^{2+} ratios in calcium carbonate minerals of foraminifera, coccoliths, bivalves, or in speleothems are used to estimate paleotemperature and environmental records as well as diagenetic alterations (e.g., Purton et al., 1999; Huang and Fairchild, 2001). The interpretation of datasets for trace element distribution in carbonate minerals is related to saturation states, precipitation rates, temperatures, and metabolisms of the organisms. Accordingly, recent studies of Elderfield et al. (2006) show a carbonate ion saturation state effect on Mg^{2+} incorporation in benthic foraminifera, and Freitas et al. (2006) show that Sr^{2+} to Ca^{2+} ratios in carbonate shell might be controlled by kinetic effects, the latter driven by seasonal variation in shell growth rate that is in turn influenced in part by seawater temperature.

Isotope geochemistry

Stable isotopes of carbon and oxygen of CO_3^{2-} molecules as well as cation isotopes in carbonate minerals are frequently considered in environmental studies to decipher the origin of components, conditions during formation, alteration effects, etc. (e.g., Ripperdan, 2001). For instance, stable oxygen isotopic fractionation between calcite and water has been widely used as a proxy for temperature and environmental changes in paleoceanography, speleology, and applied mineralogy (e.g., Dietzel, 2000; Spötl and Matthey, 2006). The basic concept is referred to the temperature sensitive oxygen isotope fractionation factor between calcite and water, $\alpha_{\text{calcite-water}} = (\delta^{18}\text{O}_{\text{calcite}} + 1,000) / (\delta^{18}\text{O}_{\text{water}} + 1,000)$. For example, Kim and O'Neil (1997) and more recently Coplen (2007) adopted from inorganic precipitation experiments and field studies the $\alpha_{\text{calcite-water}}$ values for equilibrium fractionation. From laboratory experiments and field studies it is widely accepted that the use of $\delta^{18}\text{O}$ as a temperature proxy is complicated by nonequilibrium fractionation (e.g., Kim and O'Neil,

1997; Mickler et al., 2004; Dietzel et al., 2009). In natural biogenic carbonates, the effect of growth rate on $\delta^{18}\text{O}$ values of carbonates is noticeable, with a rapid growth rate resulting in a lower $\delta^{18}\text{O}$ value (e.g., Adkins et al., 2003). Numerous temperature functions are used to estimate $\alpha_{\text{MeCO}_3\text{-water}}$ values for the respective cation content, crystal structure, and organism (e.g., Lea, 2004).

In the case of nontraditional stable isotopes, Mg and Ca isotopic distributions between aqueous cations and carbonate minerals are promising proxies to reconstruct environmental conditions during carbonate formation and to provide insight into geochemical cycles (e.g., Young and Galy, 2004; Tang et al., 2008, respectively). For example, ^{44}Ca is discriminated versus ^{40}Ca during calcium carbonate crystallization. Various models exist for the calcium isotope fractionation during precipitation of calcium carbonate from aqueous solution (e.g., Fantle and DePaolo, 2007). Although, effects of temperature, precipitation rate, crystal structure, and metabolism are identified as main factors for calcium isotope fractionation, future research is required to decipher individual fraction mechanisms.

Biom mineralization

Biom mineralization refers to the process by which living organisms form minerals. The most abundant carbonate biom minerals with respect to quantities and widespread distribution are calcium carbonates such as calcite and Mg calcite, and to a lesser extent aragonite, monohydrocalcite, and ACC (e.g., Weiner and Dove, 2003). Biom mineral phases often have shape, size, crystallinity, isotopic and trace signatures quite unlike their isotopic inorganically formed counterparts as a result of the interaction between organic macromolecules and an amorphous-crystalline phase transformation during early stages of biom mineralization. Sorting out the physiological effects from environmental signals provides a challenge for further scientific research.

Although, ACC is thermodynamically metastable it can be introduced as an important precursor of biom mineralization. Biom mineralization mechanisms and strategies for the biomimetic preparation of functional materials can be followed by transformation of ACC into crystallized calcium carbonates regulated by additives, e.g., functional polymer, proteins, and inorganic ions (Xu et al., 2008).

Han and Aizenberg (2008) showed that the ACC phase can be doped with foreign ions (e.g., Mg^{2+}) and organic molecules (e.g., dyes) and that these compounds later function as growth modifiers of calcite crystals. Such foreign components are incorporated into the crystals during the transformation process of ACC to calcite, which may indicate a vital effect on biogenically induced calcite. Lam et al. (2007) synthesized ACC in the presence of Mg^{2+} and polyaspartic acid. While the first Mg rich ACC precipitates showed short-range structures most similar to aragonite, the initial polyaspartic ACC precipitates possessed short-range structures resembling vaterite. The

influence of these additives on the crystallization of calcium carbonate is apparent even in the precipitation of the first amorphous precursor phase.

Summary

Carbonate minerals have a high diversity and are widely distributed throughout the Earth's crust. The most abundant carbonates contain calcium and magnesium such as calcite, dolomite, Mg calcite, and aragonite. For biogenically formed carbonates, precursor phases such as ACC are of special interest. In aqueous systems the stability of carbonates is related to the solubility product and the kinetics of dissolution and precipitation. Incorporation of foreign cations and isotopes into carbonates is mostly controlled by the composition of the solution, temperature, and precipitation rate. Thus, the chemical and isotopic composition of carbonates can be used as promising proxies to decipher environmental conditions during mineral formation and alteration. Lab experiments will be essential to provide insight about environmental changes throughout the geologic history from field data.

CATHODOLUMINESCENCE MICROSCOPY

Walter Vortisch

Montanuniversität Leoben, Leoben, Austria

Definition

Cathodoluminescence (CL) is the emission of visible light (also ultraviolet [UV] and infrared) of a solid material that is irradiated by an electron beam (in vacuum). During irradiation CL often changes. Besides CL, the emission of element-specific X-rays and backscattered, secondary and Auger electrons is caused (e.g., Walker and Burley, 1991). Moreover, the sample is heated by the electron beam, which represents an important cause for the alteration of CL characteristics during electron bombardment. Cathodoluminescence microscopy (CLM) combines CL with optical microscopy (in geosciences, generally polarizing microscopy). CL microscopic studies are mostly carried out on thin sections (uncovered, preferably polished), sometimes on up to one cm-thick samples, the latter preferably with polished surface as well. Depending on the instrument used (see below), samples can be studied uncoated or with a coating to avoid charging by the electron beam.

Two types of CL are known: intrinsic and extrinsic (for details see discussion by Remond et al., 2000). Intrinsic CL is purely due to lattice features, generally very weak and only visible if there are no activators present in adequate amounts. Extrinsic CL, the generally observable case, is caused by activators, which occur as trace elements. The activators may be supported by sensitizers that transmit energy to the activators. Quenchers are elements that reduce or even inhibit CL. The significance of sensitizers and quenchers is still in discussion. An important example is iron, which is generally considered as a quencher in carbonate minerals, and lead, which seems to be a sensitizer (e.g., Machel, 2000). In contrast to the view of iron as a quencher, Cazenave et al. (2003) showed in a recent study of doped calcite that Mn-activated CL in calcite can be uninfluenced by iron in a relatively wide range of iron concentrations. The question whether Pb and Zn can be sensitizers in calcite was discussed by Budd et al. (2000), who could not find any evidence for sensitizing by these trace elements.

In geosciences, CLM is a powerful tool for detailed analyses of rocks and minerals, including biogenic mineral substances (for a summary of CL data and earlier literature, see for instance Marshall, 1988, Remond et al., 1992 and Pagel et al., 2000). Intensity and wavelengths (colors) of emitted light may vary strongly for the same mineral phase or even within the same mineral grain, depending on genetically determined features. This is especially significant when a mineral substance is growing or recrystallizing under changing ambient conditions, often causing changes of CL intensity or color, sometimes revealing patterns of complex zoning. In most cases, such effects are not visible by optical microscopy. Therefore, for studies of biogenic mineral substances, CLM can

organisms are not capable of using plant litter, e.g., directly and thus entirely dependent on microbial degradation processes to have sufficient minerals available for their nutrition. Properties of microbes for degradation can be useful in bioremediation approaches.

MICROBIAL ECOLOGY OF SUBMARINE CAVES

Francesco Canganella, Giovanna Bianconi
 University of Tuscia, Viterbo, Italy

Definition

Essential concepts, current investigations, and discussion.

In recent years, the search for the limit of biodiversity in extreme and/or uncommon environments led to the investigation of peculiar ecosystems such as deep-sea, subterranean niches, Antarctic cores, hydrothermal vents, and extraterrestrial sites.

Submarine caves and cavities have also been explored, some were mainly exploited as popular attractions for scuba divers, but some were shown to be of great interest for geologists, biologists, and microbiologists.

Available scientific data on these ecosystems are not abundant, particularly as far as biological disciplines are concerned. Most of the published works have been related to specific submarine cavities known as Blue Holes and Black Holes, as well as to submarine caves showing inner sulfidic emissions. A larger number of data are currently available regarding the microbiology of terrestrial caves, particularly on the microbial ecology of carbonate layers, sediments, bat guano, and flooding waters (Vlasceanu et al., 1997, 2000; Holmes et al., 2001; Engel et al., 2003; Northup et al., 2003; Sugita et al., 2005; Zhou et al., 2007), but these latter ecosystems are not part of the current review.

Blue holes and black holes

The so-called blue holes are underwater karst systems which can develop horizontally in a very extensive way and appear blue due to a combination of blue sky reflection with the white carbonate sand deposited in the cave (Smart et al., 1988; Mylroie et al., 1995; Schwabe et al., 1997; Marano-Briggs, 2000; Colantoni et al., 2003; Canganella et al., 2004). Most of these sites were found and described in Bahamas and Hawaii.

Other cavern systems are known as “black holes,” which are cave systems without known lateral passages and located in the interior regions of the larger Bahamian islands. Most black holes are located in the central to western side of the island of South Andros in the Bahamas (Figure 1), although one has been found on the northern transitional shore of the Grand Bahama Island. They are vertical cave systems which

Microbial Ecology of Submarine Caves, Figure 1 A schematic drawing of the South Andros black hole, (a) aerial view and (b) bathymetry. UWL, upper water layer; LWL, lower water layer; —, floor area not surveyed. (Reprinted from Schwabe and Herbert, 2004 *Black Holes of the Bahamas: what they are and why they are black*, *Quaternary International* 121: 3–11 with permission from Elsevier.)

develop from the surface downward and appear to have no direct link to the sea, except through rock fissures and local porosity (Schwabe, 1998; Schwabe and Herbert, 2004).

In both cave systems, as water exchange is severely restricted, physicochemical gradients are highly stable and even strict anaerobic conditions can develop with remarkable hydrogen sulfide concentrations (from 5 μM to 6 mM).

Submarine caves with sulfidic water springs

A unique marine ecosystem is represented by the submarine caves of Capo Palinuro (Salerno, Italy), of which 13 have inside sulfidic springs exhibiting temperatures up to 25°C that remarkably affect the surrounding ecosystem.

Preliminary investigations concerning the submarine speleology of the site have been carried out since the mid 1980s, but only after 1990 an extensive biological knowledge was achieved. Several ecological and geological studies were performed (Alvisi et al., 1994a, b; Mattison et al., 1998), particularly on the “Grotta Azzurra” (Figure 2). The cave may be separated into two topographically distinct regions: a weakly illuminated outer region and an inmost dark region (Snow Hall). The latter is

characterized by the presence of sulfur springs that arise from fissures in the cave floor. Currently, no other submarine caves with sulfide springs have been reported.

Microbiological studies

The blue holes

Abundant microbial development has been observed in these cave systems, usually linked to temperature anomalies in the range of 36–41°C as recorded by investigators. Marano-Briggs (2000) reported temperatures up to 41°C in the Tarpon Blue Hole, supporting the theory that the mass population of anoxygenic phototrophic bacteria present at a specific water layer may dissipate excess light energy by heat. A dense layer of purple sulfur bacteria

Microbial Ecology of Submarine Caves, Figure 2 A drawing map of the “Grotta Azzurra” showing both entrances, halls, and freshwater circulation.

was indeed found at 4.5–5.5 m depth in the estuarine Tarpon Blue Hole and the dominant population was represented by *Chromatiaceae* species. These bacteria are capable either of photolithoautotrophic growth with sulfide or elemental sulfur under anoxic conditions in the light or of chemo-organotrophic growth under micro-oxygenic conditions in the dark. Their abundance in the site was consistent with their physiological traits, and among them a phototrophic bacterium in particular was identified as a novel strain of *Marichromatium purpuratum* that contained okenone instead of spirilloxanthin as its major carotenoid.

Recently, microbiological studies on a blue hole discovered in the Indian Ocean (Canganella et al., 2004) were preliminarily performed in order to investigate the distribution of microbial populations along the water column and in the bottom sediment of the cave. In Figure 3, the DGGE analysis carried out shows how bacterial populations are distributed among surface layers, mid- and deep-layers, indicating in particular a similar biodiversity between 30 and 50 m depth. The same was investigated by the Biolog system, particularly for anaerobic populations.

The molecular investigation showed that at surface there was a complex microbial community showing several peculiarities with respect to standard pelagic seawater. Characteristic species were *Thioalkalivibrio* and *Thioploca* within the Gamma-Proteobacteria and *Desulfosarcina* and other Delta-Proteobacteria; sequences within the Delta-Proteobacteria related to sponge symbionts were also found. Subsurface bacteria present in the water column appeared dominated by Alpha-Proteobacteria represented by sequences related to photoorganotrophs (*Rhodovibrio*-related), methanotrophs, and coral surface-related bacteria.

Near the bottom, although the Alpha-Proteobacteria were still well represented, the proportion of Delta-Proteobacteria increased. These Delta-Proteobacteria represent sulfate-reducing bacteria mainly belonging to the Desulfobacteriaceae, or related to *Desulfonanticus*, *Syntrophus*, and others related to marine and salt-marsh uncultured bacteria.

The black holes of the Bahamas

The water in these holes appears black in color due to the presence of a 1 m thick white microbial veil located within the upper third of the water column (18–19 m), at the boundary between the oxygenic low salinity upper water mass and the denser anoxic saline water layer. The boundary between the two water masses is characterized by sharp discontinuities in physicochemical gradients: salinity increased from 12 to 35 psu and temperature from 29°C to 36°C; pH decreased from 8.6 to 6.45 as well as dissolved O₂ from 6 mg/l to <1 mg/l. Morphological microscopic observations of collected samples showed mainly nonmotile spherical and motile rod-shaped purple sulfur bacteria. The dominant members of this warm (36°C), saline, and sulfide-rich layer have been identified

Microbial Ecology of Submarine Caves, Figure 3 DGGE analysis of the water column and bottom sediment of the blue hole in the Indian Ocean.

as anoxygenic phototrophic bacteria belonging to the genera *Allochromatium* and *Thiocapsa* and showed population densities $>10^7$ viable cells/ml. These bacteria grow well in the presence of sulfide and carbon dioxide in the light. During photoautotrophic growth sulfur globules are stored intracellularly as intermediate oxidation products. Moreover, the intracellular photosynthetic membranes are of the vesicular type, and bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series are present (Herbert et al., 2005). Calculations made by these authors revealed that the layer of anoxygenic phototrophic bacteria in the South Andros black hole may have a biomass content of approximately 5.06 ton dry weight.

Microbial Ecology of Submarine Caves, Figure 4 A phylogenetic tree based on 16S rRNA gene sequence comparison, including representative heterotrophic isolates from the "Grotta Azzurra."

The marine caves of Capo Palinuro

The emergence of sulfidic water in some of the caves (particularly in the "Grotta Azzurra," "Grotta Sulphurea," and "Grotta di Cala Fetente") gives rise to an unusual situation, characterized by abiotic as well as biotic fluctuations, represented by emissions from sulfidic springs and higher concentration of sulfur-utilizing bacteria following each outflowing event, respectively. Warm sulfidic water of reduced salinity enters the Snow Hall (Grotta Azzurra),

from fissures in the bottom rocks, and rises above the more dense seawater to form a thermocline and chemocline as a visible boundary at a depth of about 9.5 m. The geochemistry of water samples from the Grotta Azzurra was extensively reported by Mattison et al. (1998): above and below the chemocline temperatures were 24.0 ± 0.2 and 22.8 ± 0.3 , respectively; NaCl concentrations (%) were 2.6 ± 0.1 and 3.0 ± 0.1 , respectively; pH values were 7.22 ± 0.02 and 8.15 ± 0.25 , respectively.

Microbial Ecology of Submarine Caves, Figure 5 (a) A SEM picture of a sample collected in the bacterial mat on the vault of the “Grotta Azzurra”; (b) a SEM picture of a sample collected in the bacterial mat on the vault of the “Grotta Azzurra”; (c) A SEM picture of a sediment sample collected nearby a sulfataric spring along the main entrance of the “Grotta Azzurra.”

The present ecosystem is biologically unique particularly because of the following points: (1) the peculiar emissions represent the only available model in shallow waters resembling the deep-sea hydrothermal vents (Canganella, 2001); (2) alike what happens in usual submarine caves, the development of micro- and macro-fauna increases with the decrease of irradiation; (3) the freshwater flow is placed above the seawater and, inside the cave, an interface between the warm/anaerobic upper zone (H_2S -enriched) and the cold, sulfurless lower zone can be observed; (4) giant forms, particularly among *Cnidaria* and *Porifera*, occur mainly along the aerobic/anaerobic interface (Alvisi et al., 1994a, b).

During the last decade both, “Grotta Azzurra” and “Grotta Sulfurea” have been investigated. Some preliminary data on the lithotrophic microflora were published (Mattison et al., 1998), and other studies were performed in order to (1) investigate the microscopic structure of bacterial mat and (2) to understand both the taxonomy and physiology of heterotrophic bacteria inside the “Grotta Azzurra” (Canganella and Bianconi, 1999, 2003). The 16S rRNA genes analysis (Figure 4) showed that heterotrophic isolates were closely related to the genera *Escherichia*, *Citrobacter*, *Vibrio*, and *Bacillus*.

In addition to the analysis of the heterotrophic microflora, recently a preliminary molecular investigation was performed to evaluate the biodiversity of both eubacterial and archaeal populations (Canganella F. and Bianconi G. 2009).

Some bacterial sequences were closely related to the sulfur-oxidizing bacterial group, involving the genus *Beggiatoa* and *Thiothrix*. Showing that these microorganisms may well represent a major microbial community in the bacterial mat of the cave. Other bacterial sequences were phylogenetically linked to the Delta-proteobacterial group, particularly to sulfate-reducing bacteria. Archaeal sequences were partially related to methanogen archaeal group, but the phylogenetic distance was still remarkable; so the involvement of a novel archaeal group can be considered. Other archaeal sequences were related to MG-1,

which is a common uncultivable archaeal group in marine environment.

As regards the microscopic structure of bacterial mat inside the cave and sediments collected nearby a sulfidic spring along the main entrance of the “Grotta Azzurra,” the distribution of various morphological forms is shown in Figures 5a–c. Filamentous microbial forms were abundant and morphologically similar to *Beggiatoa*, *Desulfonema*, *Leucothrix*, or *Thiothrix* species; morphology was, however, not enough to identify such organisms. Several cells showing either coccoid or rod morphologies were also observed in samples collected inside as well as outside the mat.

Conclusions

As regards the blue and black holes, it has been shown that the dominant anoxygenic phototrophic bacteria in the microbial layers are member of the *Chromatiaceae* (Imhoff et al., 1998). The presence of dense phototrophic populations of purple sulfur bacteria particularly explains why the South Andros black hole appears black and not blue. Moreover, the sulfide profile data obtained in this site showed that sulfide concentration was low (30 μM) suggesting that biomass production by the purple sulfur bacteria was sulfide rather than light limited.

Another important point to consider is that the dense microbial phototrophic population probably plays a significant role in enhancing carbonate CO_2 -mediated dissolution operated by heterotrophic bacteria. The effects of microbiological activity on degradation of limestone deposits have been described by several authors (Ehrlich, 1996; Golubic and Schneider, 1979; Paine et al., 1993) and similar observations were reported for the Bahamas cave systems from Smart et al. (1988).

Recent studies have shown that biotic oxidation of sulfide into sulfuric acid can occur in anoxic marine ecosystems due to chemoautotrophic sulfur-oxidizing bacteria such as *Beggiatoa* (Mattison et al., 1998; Vlasceanu et al., 1997, 2000). This biological process may also be involved in carbonate dissolution for the South Andros black hole but the role of sulfur-oxidizing bacteria needs

to be evaluated by further investigations. The same consideration may be valid for the blue hole in the Indian Ocean. In this site the occurrence of highly toxic sulfide and low oxygen content caused the death of the macrobenthos in deep waters, where a chemolithoautotrophic microbial community settled on the cave walls as mucilaginous and hardened short filaments of bacterial origin whose study is still in progress.

In the "Grotta Azzurra" cave of Capo Palinuro, fluids emitted from active springs with maximum temperatures of 25°C and enriched in dissolved sulfur species (H_2S , $\text{S}_2\text{O}_3^{2-}$) allowed the development of a significant micro- and macro-fauna, resembling in some way what occurs around hydrothermal vent sites (Jeanthon, 2000; Canganella, 2001).

Morphological/physiological observations were previously carried out by Mattison et al. (1998) on microbial mats in the "Grotta Azzurra" of Capo Palinuro. In recent studies both sampling and isolation were carried out regardless of the chemocline. Future investigations on the distribution of microbial populations will eventually lead to discrimination between more thermotolerant and more mesophilic species living above or below the chemocline; the same can be true for noncultivable species.

The characterized heterotrophic isolates partially represent the microbial ecology of the site, showing its biological complexity at a phylogenetic level. Moreover, the wide resistance of isolates to temperature, salinity and pH may be associated with the specific ecological system, an hypothesis that certainly deserves further investigations.

In general terms, similar environmental traits can be described for the blue hole in the Indian Ocean and the submarine caves of Palinuro Cape; first of all, the presence of elevated concentrations of hydrogen sulfide, ranging from 5 μM to 200 mM. A chemocline in the water column may be clearly observed in the blue hole of the Indian Ocean or in the black hole of the Bahamas, whereas in the submarine caves of Palinuro Cape the environmental borderline inside the habitat is represented by the threshold between upper anoxic, sulfide-rich freshwater and lower seawater.

As regards the autoctonous microflora, the blue hole of the Indian Ocean showed the presence of filamentous forms as described in the Palinuro caves but mucilaginous forms on the rocky side walls were not found in the latter; moreover sulfate-reducers and sulfide-oxidizers were also detected in both systems.

Some microbiological features of both systems are also shared with other sulfide-rich environments, such as the presence of anaerobic methane oxidizers, filamentous bacteria, anaerobic phototrophs, and archaeal strains. However, the incomplete data set on the inhabitant microflora, the geological diversity of the systems described earlier, and their different geographical locations make a microbiological comparative study difficult. With no

doubts the combination of different approaches and techniques may be a powerful tool to investigate further such astonishing ecosystems by a multiphasic approach.

As a matter of fact, further investigations on the microbial diversity in sulfide-rich, either marine or freshwater, caves will be based on traditional techniques of isolation coupled to simultaneous molecular investigations.

MICROBIAL MATS

Joachim Reitner

University of Göttingen, Göttingen, Germany

Synonyms

Algal mats; Bacterial mats; Biomats; Thick biofilms

Definition

Microbial mats are often centimeter-thick multilayered structures of microorganisms, mainly bacteria, archaea, fungi, and sometimes these mats are enriched with protozoans. Microbial biofilms are in contrast much thinner (10–100 µm) than microbial mats and have a different architecture (Characklis and Wilderer, 1989). Microbial mats grow at interfaces between different types of material, mostly on moist surfaces, but some of them are also found in dry environments like deserts (e.g., Stal and Caumette, 1994; Characklis and Wilderer, 1989). They colonize environments located in high altitude, they are common in the Deep Biosphere, in subterranean environments with temperatures from –40°C to +120°C. There are also common as endosymbiotic structures, for example, in animals. They are very common in extreme environments like hydrothermal vents, cold seeps, and alkaline and hypersaline lakes (Van Dover, 2000; Pederesen, 2006; Arp et al., 2003; Riding and Awramik, 2000).

Geobiological implications

A microbial mat consists of several layers dominated by specific types of microorganism (Figures 1 and 2). Although the composition of individual mats varies depending on the environment, as a rule the by-products of each group of microorganisms serve as energy source for other groups. Different types of microorganisms dominate different layers based on their comparative advantage (Canfield and Des Marais, 1993; Allison et al., 2000). Ecological relationships between different groups are a combination of competition and cooperation. The metabolic capabilities of bacteria and archaea are generally depend on their phylogeny. In a wet environment where sunlight is available, the upper layers are generally dominated by aerobic consortia like cyanobacteria (Figure 1), while the lowest layers are normally dominated by anaerobic microorganisms such as sulfate-reducing bacteria, methanogenic and/or methanotrophic archaea, or general archaea. Marine mats may grow to a few centimeters in thickness, of which only the top few millimeters are oxygenated. Microbial mats are held together and bound to their substrates by sugar- and protein-rich extracellular polymeric substances (EPS), which they secrete (Decho et al., 2005; Wingender et al., 1999). In many cases, some of these microorganisms form filaments (threads), which tangle and thus increase the microbial

CHEMOLITHOTROPHY

Volker Thiel
 University of Göttingen, Göttingen, Germany

The term “Chemolithotrophy” refers to the gain of energy for cell biosynthesis and maintenance from the oxidation of inorganic compounds (= electron donors), in the absence of light (Kelly and Wood, 2006). The process was first described by the Russian microbiologist Sergej Winogradsky (1887, 1888).

Chemolithotrophy is a strategy unique to some prokaryotes (i.e., Bacteria and Archaea), the so-called chemolithotrophs. Whereas there is no known macrofauna possessing the capability of chemolithotrophy, some animals such as particular tubeworms and bivalves can form symbioses with chemolithotrophs, (e.g., at cold seeps or in hydrothermal environments). There exist many inorganic electron donors that can fuel chemolithotrophs involving geologic, biologic, and anthropogenic sources. Reduced sulfur, nitrogen and iron species and hydrogen are the most common substrates (Table 1). If chemolithotrophs are able to use

Chemolithotrophy, Table 1 Some common reactions performed by chemolithotrophs

Electron donor	Reaction	Organism	$\Delta G_0'$ (kJ/reaction)
Hydrogen	$\text{H}_2 + \frac{1}{2} \text{O}_2 \rightarrow \text{H}_2\text{O}$	Hydrogen bacteria	–237.2
Sulfide	$\text{HS}^- + \text{H}^+ + \frac{1}{2} \text{O}_2 \rightarrow \text{S}^0 + \text{H}_2\text{O}$	Sulfur bacteria	–209.4
Sulfur	$\text{S}^0 + \frac{1}{2} \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 2\text{H}^+$	Sulfur bacteria	–587.1
Ammonium	$\text{NH}_4^+ + \frac{1}{2} \text{O}_2 \rightarrow \text{NO}_2^- + 2\text{H}^+ + \text{H}_2\text{O}$	Nitrifying bacteria	–274.7
Nitrite	$\text{NO}_2^- + \frac{1}{2} \text{O}_2 \rightarrow \text{NO}_3^-$	Nitrifying bacteria	–74.1
Iron	$\text{Fe}^{2+} + \text{H}^+ + \frac{1}{4} \text{O}_2 \rightarrow \text{Fe}^{3+} + \frac{1}{2} \text{H}_2\text{O}$	Iron oxidizing bacteria	–32.9

CHERTS

Volker Thiel
 University of Göttingen, Göttingen, Germany

Chert is a sedimentary rock mainly consisting of micro- or cryptocrystalline (=submicroscopic) quartz (SiO_2) varieties.

Cherts often have an “indirect” biogenic origin as they result from re-precipitation of dissolved opal-A shells derived from microorganisms such as diatoms (diatomite, diatomaceous cherts, see also entry “*Diatoms*”) and radiolarians (radiolarite, see also entry “*Protozoa (Heterotroph, Eukaryotic)*”). Postsedimentary dissolution of these shells leads to the accumulation of silica-rich fluids within pore waters, thus, inducing precipitation of metastable cristobalite, also known as opal-CT (Konhauser, 2007). Opal-CT may, under increasing temperatures and pressures, be converted into stable quartz. Chert may also originate from microbial silification, and it may form, with or without microbial mediation, in hydrothermal environments (Konhauser et al., 2004; Jones et al., 2004, see also entries “*Sinter*” and “*Hot Springs and Geysers*”). Depending on the content of clay and other minerals, chert may grade into siliceous shales or -mudstones. The color of cherts may vary greatly with the content of accessory elements. Iron (hematite), for instance, gives rise to red varieties called “jasper.” Banded cherts, with often colorful, rhythmic layers, are called “agate.”

Chert may occur as extensive layers (bedded cherts) within sedimentary formations as well as in concretionary

CHERTS

Volker Thiel
 University of Göttingen, Göttingen, Germany

Chert is a sedimentary rock mainly consisting of micro- or cryptocrystalline (=submicroscopic) quartz (SiO_2) varieties.

Cherts often have an “indirect” biogenic origin as they result from re-precipitation of dissolved opal-A shells derived from microorganisms such as diatoms (diatomite, diatomaceous cherts, see also entry “*Diatoms*”) and radiolarians (radiolarite, see also entry “*Protozoa (Heterotroph, Eukaryotic)*”). Postsedimentary dissolution of these shells leads to the accumulation of silica-rich fluids within pore waters, thus, inducing precipitation of metastable cristobalite, also known as opal-CT (Konhauser, 2007). Opal-CT may, under increasing temperatures and pressures, be converted into stable quartz. Chert may also originate from microbial silification, and it may form, with or without microbial mediation, in hydrothermal environments (Konhauser et al., 2004; Jones et al., 2004, see also entries “*Sinter*” and “*Hot Springs and Geysers*”). Depending on the content of clay and other minerals, chert may grade into siliceous shales or -mudstones. The color of cherts may vary greatly with the content of accessory elements. Iron (hematite), for instance, gives rise to red varieties called “jasper.” Banded cherts, with often colorful, rhythmic layers, are called “agate.”

Chert may occur as extensive layers (bedded cherts) within sedimentary formations as well as in concretionary

nodules. For example, vast deposits of bedded cherts, alternating with iron minerals, are found within the Precambrian “Banded Iron Formations” (see entry). “Flintstones” on the other hand, are dark-colored chert nodules that precipitated in chalk such as in the Upper Cretaceous Maastrichtian Formation in Middle Europe. Here, the SiO₂ mainly derived from diagenetically dissolved, and re-precipitated, sponge spicules. Deposits with a high content of sponge-derived SiO₂ dispersed in sedimentary rocks are called “spiculites.”

Cherts may provide an excellent matrix for the long-term preservation of macro- and microfossils as well as chemical and isotopic signatures, due to their density and resistance. Examples are the Rhynie Chert that uniquely preserved an early Devonian community of plants, animals, bacteria, and fungi (Taylor et al., 2009), and numerous Precambrian cherts that provide an exciting view on the early dawn of life on Earth (Derenne et al., 2008; Westall et al., 2006, see entry “*Biosignatures in Rocks*”).

CHONDRITES

Chondrites are the most common class of stony meteorites. Chondrites largely consist of iron- and magnesium silicate minerals and remain unaffected from melting and differentiation. Therefore, chondrites are considered to reflect the elemental composition of the original solar nebula. *Carbonaceous chondrites* are a rare variety of chondrites containing numerous organic compounds, including amino acids. See “*Meteoritics*” for further reading.

CHROOCOCCIDIOPSIS

Burkhard Büdel

University of Kaiserslautern, Kaiserslautern, Germany

The unicellular cyanobacterial genus *Chroococcidiopsis* was first described by Geitler (1933) from Sumatra, where it was found in warm springs.

Definition

The cyanobacterial genus *Chroococcidiopsis* is defined as having more or less spherical cells surrounded by a thin, firm, colorless, sometimes layered extra-cellular polysaccharide sheath (EPS). The cell has an S-layer of a special ribbon-like type, not found in other cyanobacteria so far (Büdel and Rhiel, 1985). It often occurs in large agglomerations of spherical or irregular shape. Fully grown cells (usually 2–6 µm in diameter) divide in two modes: (1) after one or two binary divisions with planes rectangular to each other, resulting daughter cells continue to divide in different planes without intermediate growth (successive multiple divisions); (2) by successive or almost spontaneous irregular cell division (multiple fission) without intermediate growth. In both types, the final daughter cells are very small (1–3 µm in diameter) and are released by rupture of the sheath envelope.

Presently, the genus *Chroococcidiopsis* comprises 14 different species (Komárek and Anagnostidis, 1998). *Chroococcidiopsis* is closely related to the heterocyst-containing, filamentous cyanobacteria (Nostocales, Stigonematales, see entry “*Cyanobacteria*”) and forms their natural sister group (Fewer et al., 2002). The current species concept needs revision.

In terms of ecology, *Chroococcidiopsis* is most interesting because of the wide variety of habitats it colonizes. Among these are different extreme biotopes such as thermal or mineral springs (see entry “*Hydrothermal Environments, Terrestrial*”), and extremely hot and cold deserts (Antarctica), where it is epilithic or endolithic on rocks (Figure 1a–h; see entry “*Endoliths*”). The genus is a common photobiont of the cyanolichens of the

nodules. For example, vast deposits of bedded cherts, alternating with iron minerals, are found within the Precambrian “Banded Iron Formations” (see entry). “Flintstones” on the other hand, are dark-colored chert nodules that precipitated in chalk such as in the Upper Cretaceous Maastrichtian Formation in Middle Europe. Here, the SiO₂ mainly derived from diagenetically dissolved, and re-precipitated, sponge spicules. Deposits with a high content of sponge-derived SiO₂ dispersed in sedimentary rocks are called “spiculites.”

Cherts may provide an excellent matrix for the long-term preservation of macro- and microfossils as well as chemical and isotopic signatures, due to their density and resistance. Examples are the Rhynie Chert that uniquely preserved an early Devonian community of plants, animals, bacteria, and fungi (Taylor et al., 2009), and numerous Precambrian cherts that provide an exciting view on the early dawn of life on Earth (Derenne et al., 2008; Westall et al., 2006, see entry “*Biosignatures in Rocks*”).

CHONDRITES

Chondrites are the most common class of stony meteorites. Chondrites largely consist of iron- and magnesium silicate minerals and remain unaffected from melting and differentiation. Therefore, chondrites are considered to reflect the elemental composition of the original solar nebula. *Carbonaceous chondrites* are a rare variety of chondrites containing numerous organic compounds, including amino acids. See “*Meteoritics*” for further reading.

CHROOCOCCIDIOPSIS

Burkhard Büdel

University of Kaiserslautern, Kaiserslautern, Germany

The unicellular cyanobacterial genus *Chroococcidiopsis* was first described by Geitler (1933) from Sumatra, where it was found in warm springs.

Definition

The cyanobacterial genus *Chroococcidiopsis* is defined as having more or less spherical cells surrounded by a thin, firm, colorless, sometimes layered extra-cellular polysaccharide sheath (EPS). The cell has an S-layer of a special ribbon-like type, not found in other cyanobacteria so far (Büdel and Rhiel, 1985). It often occurs in large agglomerations of spherical or irregular shape. Fully grown cells (usually 2–6 µm in diameter) divide in two modes: (1) after one or two binary divisions with planes rectangular to each other, resulting daughter cells continue to divide in different planes without intermediate growth (successive multiple divisions); (2) by successive or almost spontaneous irregular cell division (multiple fission) without intermediate growth. In both types, the final daughter cells are very small (1–3 µm in diameter) and are released by rupture of the sheath envelope.

Presently, the genus *Chroococcidiopsis* comprises 14 different species (Komárek and Anagnostidis, 1998). *Chroococcidiopsis* is closely related to the heterocyst-containing, filamentous cyanobacteria (Nostocales, Stigonematales, see entry “*Cyanobacteria*”) and forms their natural sister group (Fewer et al., 2002). The current species concept needs revision.

In terms of ecology, *Chroococcidiopsis* is most interesting because of the wide variety of habitats it colonizes. Among these are different extreme biotopes such as thermal or mineral springs (see entry “*Hydrothermal Environments, Terrestrial*”), and extremely hot and cold deserts (Antarctica), where it is epilithic or endolithic on rocks (Figure 1a–h; see entry “*Endoliths*”). The genus is a common photobiont of the cyanolichens of the

Chroococcidiopsis, Figure 1 *Chroococcidiopsis* endolithic in rocks. (a) Sandstone of the Clarens formation, Golden Gate Highlands National Park, South Africa. (b) Tshipise Sandstone Plateau, Limpopo Province, South Africa. (c) Beacon Sandstone, Dry Valleys, Antarctica. (d) Cocconino Sandstone, Colorado Plateau, Arizona, USA. Lichinomycetes group (see entry “*Fungi and Lichens*”), mostly growing on rock surfaces of hot deserts. As an endolith, it contributes to biogenic weathering (see entry “*Bioerosion*”) of silicate rocks by photosynthetic alkalization (Büdel et al., 2004).

CLAY AUTHIGENESIS, BACTERIAL

Kurt O. Konhauser
 University of Alberta, Edmonton, Alberta, Canada

Definition

The formation of clay minerals in situ through the direct or indirect action of bacteria.

Overview

Clays are one of the largest and most diverse assemblage of minerals known. The vast majority of clay minerals are aluminum silicate in composition, with various other cations substituted into the crystal lattice. The replacement of either Si or Al can lead to an excess of negative charge, which is either neutralized by the adsorption of additional cations onto the outer mineral surfaces or within the interlayer spaces.

Within the past 2 decades, field studies have led to the general recognition that bacteria can mediate the formation of clay minerals. Some clays form as replacement products from the alteration of primary minerals. In this regard, the bacterial community growing on the rock surface potentially function initially as the weathering agents (through the production of organic acids or ligands that facilitate mineral dissolution) and later as reactive surfaces for the nucleation of secondary clay phases. For instance, Konhauser et al. (2002) documented that highly altered rocks found within active steam vents at Kilauea Volcano, Hawaii, contained bacteria with small (<500 nm in diameter) grains of smectite $[(\text{Al}_{1.6}\text{Fe}_{0.4})(\text{Si}_{3.8}\text{Al}_{0.2})\text{O}_{10}(\text{OH})_2\cdot\text{K}_{0.2}]$ attached directly to the outer cell walls.

exist. First, clays provide a good source of exchangeable inorganic nutrients readily available to microbes (Tazaki et al., 1994). Second, clays such as montmorillonite stimulate the respiration of bacteria by maintaining the pH and water content of the environment at a level suitable for growth (Stotzky and Rem, 1966). Third, the formation of an external mineralized matrix may protect the living cells from the detrimental effects of toxin-producing microorganisms (Habte and Barrion, 1984) and predation by grazing protozoans (e.g., Heynen et al., 1988).

Summary

Microorganisms are commonly associated with fine-grained (Fe, Al)-silicates of variable composition. The inorganic phases develop in a predictable manner, beginning with the adsorption of cationic iron to anionic cellular surfaces, supersaturation of the proximal fluid with Fe (III), nucleation and precipitation of a precursor ferric hydroxide phase on the cell surface, followed by reaction with dissolved silica and aluminium, and eventually the growth of an amorphous clay-like phase.

COCCOLITHOPHORES

Volker Thiel

University of Göttingen, Göttingen, Germany

Coccolithophores (coccolithophorids) are a group of unicellular, marine, planktonic algae belonging to the haptophytes (Prymnesiophyta). The coccolithophores are capable of controlling the intracellular precipitation of calcite onto organic plates and the assembly of the mature carbonate scales at the cell surface. These scales, the coccoliths, are spherical or oval, often intricately patterned and generally less than 20 µm in diameter. Given the abundance of coccoliths in sediments, coccolithophorids have been playing a major role in the global carbon budget. They were very abundant in the Mesozoic era, particularly in the Cretaceous period, in which they became a major component of the “Chalk” lithology (e.g., White Cliffs of Dover, England). Today, coccolithophorids are accounting for about a third of the total marine CaCO_3 production, and coccoliths are a major component of the

modern deep-sea calcareous oozes. The most widespread modern species is *Emiliania huxleyi*. Recent studies showed that calcification and net primary production in *E. huxleyi* have increased by ~40% over the last 220 years due to ocean acidification in response to rising atmospheric CO₂ partial pressures (Iglesias-Rodriguez et al., 2008). Contributions of sedimentary organic matter from coccolithophorids, and other haptophyte algae, can be tracked by particular lipid biomarkers, the long-chain alkenones. These compounds are often used as a “paleothermometer” for the estimation of past sea surface temperatures (see entry “*Biomarkers (Organic, Compound-Specific Isotopes)*”). For detailed reading and further references please see entry “*Algae (Eukaryotic)*.”

COLD SEEPS

Robert G. Jenkins
Yokohama National University, Yokohama City, Japan

Synonyms

Diffusive seep; Ground water seep; Hydrocarbon seep; Methane seep; Oil seep. The terms “seep” and “seepage” can be used as alternates

Definition

Fluid flow containing reduced compounds, e.g., methane or hydrogen sulfide (see entry *Sulfur Cycle*), with almost no temperature anomalies compared with ambient seawater gushing out from or reaching very close proximity to the seafloor.

Introduction

Active water circulation systems can be found at seafloor level and beneath the seafloor along the plate boundaries such as mid-ocean ridges and trenches. It is well known that at ocean ridges, hydrothermal fluid containing reduced compounds and minerals vent out from the seafloor. In contrast to the hydrothermal vents, focused flow containing reduced compounds, e.g., methane and hydrogen sulfide, gushing out from the seafloor can also be found along active and passive continental margins and around diapirs of serpentine and salt rock (halite) with no or less temperature anomalies compared to the ambient seawater. This fluid flow is called a cold seep.

The first cold seep was found at the Florida Escarpment off Oregon in 1984 by the submersible Alvin (Paull et al., 1984). The Alvin found a large number of alleged tube

worms and white clams which were thought to be highly endemic to hydrothermal vents. It turned out that there are fluid flows which contain reduced compounds and which support chemosynthesis-based life, similar to hydrothermal vents (Kulm et al., 1986).

Examples of the reduced compounds contained in cold seeps are methane and hydrogen sulfide. These compounds lead to extensive biogeochemical reaction when the fluid encounters oxic interstitial water which has penetrated into sediments from seawater. The reaction is mainly mediated by microbes as a way of obtaining chemosynthetic energy to synthesize their organic compounds. Primary production based on the chemosynthesis found in cold seeps results in the formation of characteristic life forms similar to those which can also be found in hydrothermal vents.

The important role played by methane in global warming is due to the fact that the greenhouse effect that results from it is more than 20 times that of carbon dioxide (Kvenvolden, 1988). Hence if we think of cold seeps as a pipe connecting the deep subsurface and the oceans, we can understand their importance in terms of global climate change and biogeochemical cycles at the sediment–water interface.

Distribution

Cold seeps are widely distributed along the active and passive continental margins of the world’s oceans (Figure 1; Sibuet and Olu, 1998; Levin, 2005). The depth range of a cold seep varies from shallow water less than 15 m (Montagna and Spies, 1985) to deep water more than 7,400 m in the Japan Trench (Fujikura et al., 1999).

The total number of cold seeps reported to date represent a minimum, because finding a cold seep is significantly more difficult than finding a hydrothermal vent. The difficulties of identification result from the natural characteristics of cold seeps which are difficult to observe by the use of a submersible or remote operated vehicle (ROV).

Natural characteristics of cold seeps

Cold seeps vary in accordance with their natural characteristics. Most cold seeps are very calm, i.e., the low seepage intensity and low fluid flow rate has no effect on the sea floor. The almost total absence of any temperature anomaly in relation to the ambient seawater also makes it difficult to distinguish the flow by visual observation. The occurrence of chemical anomalies is found over too narrow an area and the anomalies usually occur only in the sediment. Thus, this kind of calm cold seep, called a diffusive seep, is rather difficult to find on the basis of geological and geochemical signatures which exist only beneath the sea floor. One good indicator pointing to the existence of a cold seep is the occurrence of chemosynthesis-based life obtaining energy from the reduced compounds contained in the seep fluids (Sibuet and Olu, 1998). Such biota often comprises large bivalves and/or

modern deep-sea calcareous oozes. The most widespread modern species is *Emiliania huxleyi*. Definition

Fluid flow containing reduced compounds, e.g., methane or hydrogen sulfide (see entry *Sulfur Cycle*), with almost no temperature anomalies compared with ambient seawater gushing out from or reaching very close proximity to the seafloor.

Introduction

Active water circulation systems can be found at seafloor level and beneath the seafloor along the plate boundaries such as mid-ocean ridges and trenches. It is well known that at ocean ridges, hydrothermal fluid containing reduced compounds and minerals vent out from the seafloor. In contrast to the hydrothermal vents, focused flow containing reduced compounds, e.g., methane and hydrogen sulfide, gushing out from the seafloor can also be found along active and passive continental margins and around diapirs of serpentine and salt rock (halite) with no or less temperature anomalies compared to the ambient seawater. This fluid flow is called a cold seep.

The first cold seep was found at the Florida Escarpment off Oregon in 1984 by the submersible Alvin (Paull et al., 1984). The Alvin found a large number of alleged tube

worms and white clams which were thought to be highly endemic to hydrothermal vents. It turned out that there are fluid flows which contain reduced compounds and which support chemosynthesis-based life, similar to hydrothermal vents (Kulm et al., 1986).

Examples of the reduced compounds contained in cold seeps are methane and hydrogen sulfide. These compounds lead to extensive biogeochemical reaction when the fluid encounters oxic interstitial water which has penetrated into sediments from seawater. The reaction is mainly mediated by microbes as a way of obtaining chemosynthetic energy to synthesize their organic compounds. Primary production based on the chemosynthesis found in cold seeps results in the formation of characteristic life forms similar to those which can also be found in hydrothermal vents.

The important role played by methane in global warming is due to the fact that the greenhouse effect that results from it is more than 20 times that of carbon dioxide (Kvenvolden, 1988). Hence if we think of cold seeps as a pipe connecting the deep subsurface and the oceans, we can understand their importance in terms of global climate change and biogeochemical cycles at the sediment–water interface.

Distribution

Cold seeps are widely distributed along the active and passive continental margins of the world's oceans (Figure 1; Sibuet and Olu, 1998; Levin, 2005). The depth range of a cold seep varies from shallow water less than 15 m (Montagna and Spies, 1985) to deep water more than 7,400 m in the Japan Trench (Fujikura et al., 1999).

The total number of cold seeps reported to date represent a minimum, because finding a cold seep is significantly more difficult than finding a hydrothermal vent. The difficulties of identification result from the natural characteristics of cold seeps which are difficult to observe by the use of a submersible or remote operated vehicle (ROV).

Natural characteristics of cold seeps

Cold seeps vary in accordance with their natural characteristics. Most cold seeps are very calm, i.e., the low seepage intensity and low fluid flow rate has no effect on the sea floor. The almost total absence of any temperature anomaly in relation to the ambient seawater also makes it difficult to distinguish the flow by visual observation. The occurrence of chemical anomalies is found over too narrow an area and the anomalies usually occur only in the sediment. Thus, this kind of calm cold seep, called a diffusive seep, is rather difficult to find on the basis of geological and geochemical signatures which exist only beneath the sea floor. One good indicator pointing to the existence of a cold seep is the occurrence of chemosynthesis-based life obtaining energy from the reduced compounds contained in the seep fluids (Sibuet and Olu, 1998). Such biota often comprises large bivalves and/or

Cold Seeps, Figure 1 Distribution of modern and ancient cold seeps and hydrothermal vents. (After Campbell, 2006.)

worm tubes which are clearly visible (Figure 2). However, seep-associated infaunal animals (i.e., animals living only in the sediments) and microorganisms are potentially difficult to detect.

Direct measurements of cold seep fluid chemistry started around the end of the last century (e.g., Tryon and Brown, 2001, 2004). The results show that the fluid pattern and rate of flow are more complex than was previously thought to be the case. Although most cold seeps are calm, there are some effusive and explosive cold seeps. When the saturation level of dissolved methane in sea water is exceeded, the excess methane forms gas bubbles (Figure 3) or gas hydrate (Figure 4) depending on the physical conditions. The bubbly gaseous methane can be found by visual observation (Figure 2) and also by hydroacoustic sounders, like a fisheries sonar (Figure 5; Paull et al., 2007; Aoyama and Matsumoto, 2009). The acoustic sounder makes it possible to see the plume due to the relatively low density of the methane bubbles compared to the ambient sea water. In waters off Niigata, Sea of Japan, methane bubble streams venting out from the sea floor at about 900 m water depth produce a plume

reaching to about 300 m below the sea surface (Figure 5; Aoyama and Matsumoto, 2009).

Cold seeps associated with a mud volcano or serpentine diapir show that the flow gushes out together with muddy sediment or brecciated serpentine rocks. It may also happen that methane erupts from the seafloor due to a pressure increase in the sediments caused by an accumulation of methane gas. Such an eruption forms chaotic structures of strata, like landslides, and crater-like topographically depressed areas, so-called pock marks. The size of a pock mark may vary from a few meters to a few hundred meters in diameter and from 1 m to 80 m in depth (Gay et al., 2006).

Pathway and migration of fluid flow

Generally, reduced compounds increase with depth in marine sediments. These reduced compounds can be oxidized by oxidants such as oxygen, nitrate, and sulfate and usually occur at a shallow depth under the sea floor. Although these reactions do also occur elsewhere below the sea floor, substantial reaction occurs in cold seeps

Cold Seeps, Figure 2 Cold seep in the Kuroshima Knoll, Okinawa, southwestern Japan. A dense colony of bathymodiolian bivalves, housing chemosynthetic microbes, covered the sea floor. Gushing out of gaseous bubbly methane can be seen. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

Cold Seeps, Figure 3 Collecting methane gas bubbles at a cold seep. ROV Hyper-dolphin collected the bubbly methane gas venting out from the cold seep in the waters off Joetsu, Sea of Japan. Putative shell-like gas hydrate covers each gas bubble. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

Cold Seeps, Figure 4 Outcrop observation of gas hydrate in the waters off Joetsu, Sea of Japan. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

because of the high amounts of reduced compounds brought up to the sea floor from the deep subsurface. Accumulation and migration of reduced compounds are required to form a cold seep.

The pore water containing reduced compounds favors migration through physically weak paths, e.g., faults, and permeable sediments. Tectonic stresses, e.g., plate subduction or diapirs, induce the formation of such pathways. Thus, occurrences of cold seeps are largely dependent on the tectonic background of the area concerned.

Cold seep pathways take the form of a fault or faulted anticline, salt or serpentine diapirs, or a cut bank of strata. These structures can be revealed by seismic profiles, direct observations of the outcrops in the ocean, and drill core samples with chemical profiles of the pore water (Figure 6; Moore et al., 1990, 2001).

Iodine radioisotopes (see entry *Isotopes, Radiogenic*) have recently been identified as a useful tool to determine the age of the strata from which the methane originated, as the iodine will be released at the same time as methane is generated from organic matter, and the diffusion rates of methane and iodine are very similar (Fehn et al., 2003).

For example, pore water from a cold seep in the Japan Sea passed through and probably originated from strata which sedimented during 30–20 Ma (Tomaru et al., 2007). Faults associated with cold seeps occur particularly on the landward wedge of subduction zones, e.g., the Barbados accretionary wedge, the Cascadia margin and the Japan Trench. Faults created by tectonic stress due to subduction of

Cold Seeps, Figure 5 Methane plumes observed by acoustic sounder at the Umitaka spur, off Joetsu, Sea of Japan. The plumes rose up from the sea floor at depths ranging from ca. 900 m to ca. 300 m. The horizontal axis indicates time. The vehicle obtaining the echogram ran from north to south. (Modified from Aoyama and Matusmoto (2009) (Patent no. US 7539081 B2, Seabed resource exploration system and seabed exploration method by Chiharu Aoyama).

plates play the role of physically weak pathways for the fluid flow. It may also happen that faults cut through a methane reservoir formed under impermeable strata, and the methane then migrates upward through the fault. Indeed, the direction formed by *Calymene* (bivalve) colonies, which mostly live in cold seeps and/or hydrothermal vents, is coincident with a theoretical stress fracture pattern caused by subduction tectonics (Ogawa et al., 1996).

The main driving forces of the migration of pore water containing reduced compounds are density differences and the compression of pore water by increasing pressure within the sediments. The buoyancy of gaseous and dissolved methane and light hydrocarbons in pore water is the main driving force for upward migration. Gaseous methane, the main hydrocarbon gas in the fluid flow, has a strong buoyancy, for example, the density of gaseous methane beneath 3–4 km of water is $200\text{--}300\text{ kg m}^{-3}$ compared with $1,024\text{ kg m}^{-3}$ for seawater (Clennell et al., 2000). Water in which methane is dissolved is also lighter than methane-free water. Thus, the pore water containing gaseous and dissolved methane potentially tends to migrate upward within permeable sediments. Entrapment of the fluid usually occurs where impermeable sediments are found. When strata composed of impermeable sediment are tilted, the fluid migrates within the permeable sediment in a lateral-upward direction directly beneath the impermeable strata. Thus, the hinge zone of an anticline is suitable for the accumulation of methane contained in pore water. Methane-rich fluids may further migrate upwards through faults that cut through the impermeable strata. The fluid also gushes out from outcrops where there is a break in the strata caused by erosion.

Cold Seeps, Figure 6 Interpreted seismic reflection obtained from accretionary prism, off Oregon. Rigid arrows indicate inferred flow paths for fluids. Direct measurements of bedding from the submersible Alvin correlate well with the seismic reflection lines. (After Moore et al., 1990.)

Increasing pressure arising from compaction due to continuous loading of sediments or tectonic stress squeezes out pore water containing reduced compounds into overlying strata. The increasing pressure causes not only pore water migration but also mud diapirs. This is why mud diapirs (or mud volcanoes) are often associated with methane or other reduced compounds.

Heating of the pore water is the other factor causing upward fluid migration. Heating occurs as a result of geothermal activities in the deep subsurface. After heating by geothermal activity in the deep subsurface, the temperature of the fluid drops during upward migration. Thus, the fluid temperature at sea floor level shows no or fewer anomalies in contrast to hydrothermal vents.

Migration of reduced compounds is also caused by diffusion. Although diffusion can be considered as a factor much less important than buoyancy and pressure increase, it is important for the penetration of oxidants from the sea water into sediments.

Chemistry of fluid flow

Major reduced compounds in the fluid flow in cold seeps are methane and other light hydrocarbons, hydrogen sulfide, ammonia, reduced iron, barium, and hydrogen (e.g., Tunnicliffe et al., 2003; Tryon and Brown, 2004). Methane is the most important by virtue of the fact that it is the most common hydrocarbon gas in marine sediments. Methane has a pronounced greenhouse effect and plays an important role both as an energy source and as a carbon source for microbes; furthermore, the anaerobic oxidation of methane (AOM) coupled with sulfate reduction produces hydrogen sulfide which acts as a major energy source for chemosynthesis-based ecosystems.

Elements contained in the fluid flow change with the depth of sediments, because the generation and consumption occur at different depths. Concentrations of reduced compounds generally increase in line with the depth of the sediments. Drastic changes in the chemical profile occur at shallower depths where the reduced compounds encounter oxidants. These reactions take place mainly within sediments, but it sometimes happens that the reduced compounds discharge directly into the sea water column. In such a case, the oxidation reactions take place within the water column.

The drastic chemical changes in cold seeps are generally responsible for substantial biological activities. Methane, the major reduced compound in a cold seep, is generated at a relatively deep subsurface level under anaerobic conditions. When a fluid flow containing methane migrates toward the sea floor and encounters oxidants such as oxygen and sulfate (see entry *Sulfur Cycle*) which penetrated into the sediment from oxic sea water, intensive biogeochemical reactions occur. The most important and extensive of these is AOM which occurs where the methane and sulfate coexist in anaerobic conditions. Following the AOM, oxidation of hydrogen sulfide, formation of pyrite (see entry *Iron Sulfide Formation*), and

precipitation of carbonate minerals occur. When the fluid flow gushes out into well-oxygenated conditions, aerobic oxidation of methane (*Methane Oxidation (Aerobic)*) occurs.

The origin of methane

There are several pathways for the generation of methane of which biogenic and thermogenic processes are the most important. In the case of the former, the methane is produced directly by microbes, and in the case of the latter, the methane is produced through the thermal degradation of organic compounds in the deep subsurface. Methane that is produced neither from organic material nor through organic processes can be found mainly along the edge of hydrothermal vent fields and above serpentine diapirs.

Biogenic methane

Biogenic methane is produced by microbes. The methanogenic microbes (methanogens) belong to the phylum Euryarchaeota within the domain Archaea. Methanogens are obligatory anaerobes, meaning that they live in an anoxic environment which usually occurred below the zone of sulfate reduction. The main substrates linked to the generation of methane are simple carbon-containing molecules such as carbon dioxide, formate, acetate, methanol, and methylamine (Whiticar, 1999). The two simple pathways of methanogenesis, i.e., carbonate reduction and acetate fermentation, are expressed as $\text{CO}_2 + 8\text{H}^+ \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$ and $\text{CH}_3\text{COOH} \rightarrow \text{CH}_4 + \text{CO}_2$, respectively. Archaeal methanogenesis promotes large fractionations of carbon isotopes. The stable carbon isotopic composition of methane produced by carbonate reduction generally ranges from -60 to -80‰ (vs. PDB), while the methane produced by the fermentation process ranges from -50 to -60‰ (vs. PDB; Whiticar, 1999). The methane is mostly a unitary hydrocarbon product of the biological process, whereas the thermogenic process explained below produces methane as well as other hydrocarbons such as ethane and propane. However, the recent suggestion that ethane and propane are also produced biologically (Hinrichs et al., 2006) upset the long-held concept of the origin of light hydrocarbons larger than methane, which were thought to be generated by the thermal degradation of organic matter only. The biogenic process is carried out at a relatively shallow depth compared to where thermogenic methane is produced. This is due to the presence of appropriate thermodynamic conditions, i.e., not too high a temperature and pressure, to permit microbial activities.

Thermogenic methane

The methane generated through the degradation of sedimentary organic matter as a result of thermodynamic conditions is called thermogenic methane (Kotelnikova, 2002). The rising temperature and pressure of sediments that accompany the increasing depth accelerates the

degradation of organic compounds. Thus, the production of thermogenic methane generally increases in proportion to the depth of the sediments, usually more than a few hundred meters below the seafloor. Contrarily, a high temperature inhibits microbial activities at a deep subsurface level, thus it follows that the dominant methane in the deep subsurface is thermogenically generated. This process produces not only methane but also ethane, propane, and other light hydrocarbons. There are fewer isotopic effects on carbon and hydrogen from methane produced by thermal maturation compared to biogenic methane. Thus, the carbon isotopic composition of thermogenic methane ranges from -20 to -50‰ (vs. PDB; Whiticar, 1999).

Abiogenic methane

Methane produced from inorganic matter through an inorganic process is called abiogenic methane. Such methane is thought to be generated through the processes of cooling and degassing of mafic igneous rocks and magma and the process of serpentinization of ultramafic rocks. Although the exact mechanism of abiogenic methane formation is still not fully understood, some abiogenic methane formation processes have been revealed (e.g., Horita and Berndt, 1999; Proskurowski et al., 2008). We can now say that abiogenic methane is probably the dominant methane source in hydrothermal vent systems especially along mid-ocean ridges and above serpentine diapirs.

Identification of the origin of methane

Looking specifically at the methane in cold seeps, it has been thought that this originated from the processes of biogenesis and/or thermogenesis. Most abiogenic methane will be found at hydrothermal vents and not at cold seeps except in the case of cold seeps associated with serpentine diapirs. Means of allowing us to estimate the origin of methane are a combination of analyses of the carbon isotopic compositions of the methane and the relative abundance of ethane and propane compared to the amount of methane included in fluid seepage (Schoell, 1988). Specifically, extremely negative carbon isotope values of methane, generally less than -50‰ (vs. PDB), with a high methane/(ethane + propane) ratio indicate that the methane was generated by a biogenic process. In contrast, less negative carbon isotopic composition, generally -20‰ to -50‰ (vs. PDB), with a relatively low methane/(ethane + propane) ratio indicates that the methane was generated by a thermogenic process.

Anaerobic oxidation of methane (AOM)

AOM is a key reaction at cold seeps. Although several probable reactions have been proposed (Valentine, 2002), the details of the AOM reaction are not yet clearly understood. What we can say is that the net reaction of the AOM is expressed as $\text{CH}_4 + \text{SO}_4^{2-} \rightarrow \text{HCO}_3^- + \text{HS}^- + \text{H}_2\text{O}$. Thus, the relative amounts of both sulfate and methane regulate the activity of AOM. This reaction occurs

widely in oceans because large amounts of sulfate are contained in sea water whereas the reaction will not occur in freshwater environments such as ponds, lakes, rivers, and rice fields because freshwater lacks sulfate (Whiticar, 1999). It has recently been recognized that AOM by sulfate reduction is carried out by consortia of anaerobic methane-oxidizing archaea and sulfate-reducing bacteria (Elvert et al., 1999; Boetius et al., 2000; Orphan et al., 2001, 2004). The anaerobic methane-oxidizing archaea (ANME) are found in three different phylogenetic clusters belonging to the Euryarchaeota, i.e., ANME-1, -2, and -3. It has also been revealed by genome analysis that methane is oxidized under anoxic conditions by means of a “reverse methanogenesis” process (Hallum et al., 2004). The ecology of each of these archaeal lineages (ANME-1, -2, and -3) differs from that of the others. Thus, the differences reflect their distribution pattern in cold seeps (Elvert et al., 2005; Knittel et al., 2005).

An important function of the AOM reaction is that it prevents the escape of methane, which has a pronounced greenhouse effect, from sediments into the ocean and the atmosphere. The carbon derived from methane is transformed into bicarbonate or carbonate ions. An increase in the ions leads to an increase in alkalinity and thus to the subsequent precipitation of carbonate minerals given the existence of calcium or other appropriate cations (explained below).

Oxidation of sulfides

The hydrogen sulfide (see entry *Sulfide Mineral Oxidation*), a byproduct of the AOM, is used for subsequent reactions. One is the oxidation of sulfides mediated by sulfur-oxidizing bacteria under (sub)oxic conditions, and the other is the formation of pyrite (see entry *Iron Sulfide Formation*) in anoxic conditions. Sulfur-oxidizing (thiotrophic) bacteria, such as *Beggiatoa* (qv), *Thiothrix*, and *Thioploca*, use the hydrogen sulfide as an electron donor and oxidize it by oxygen. The final product of the reaction is sulfate. Most sulfur-oxidizing bacteria are chemolithoautotrophs, but some can use organic compounds for their cell synthesis. The thiotrophic bacteria sometimes form white mats that cover the sea floor and some may live as symbiotic bacteria in animal tissues (e.g., in gills).

Aerobic oxidation of methane (qv)

The aerobic oxidation of methane (see entry *Methane Oxidation (Aerobic)*) is performed by methane-oxidizing (methanotrophic) bacteria, whereas archaea are responsible for AOM. When the methane is released directly into an oxic water column, it will be aerobically oxidized by these methanotrophs. However, in normal marine environments, methane is mostly oxidized anaerobically by AOM within the sediments. Aerobic oxidation of methane becomes important when methane vents out vigorously into oxic sea water.

Authigenic mineral precipitation in cold seeps (qv “microbial mineralization” and “microbially induced sedimentary structures”)

One result of the substantial biological reactions referred to above is the precipitation of several minerals. The minerals most commonly found in cold seeps are carbonate such as aragonite, high magnesian calcite, and low magnesian calcite. The precipitation of these carbonates occurred because of increasing alkalinity resulting from AOM. When AOM occurs at sea-floor level or above the sea floor in euxinic waters, reef-like carbonate build-ups may be formed on the sea floor, as in the Black Sea (Michaelis et al., 2002). Under an oxic water column, the reaction generally occurred within the sediment, thus the carbonate formed beneath the sea floor. At a shallower depth below the sea floor, aragonite and high magnesian calcite can be formed, whereas low magnesian calcite and dolomite are frequently found relatively deeper within the sediments (e.g., Takeuchi et al., 2007). Methane-derived carbonate bodies are sometimes exposed on the sea floor because of surface erosion. Then the carbonate may function as a hard substrate for sessile organisms or carbonate borers.

Pyrite is another common authigenic mineral found in cold seeps. Hydrogen sulfide produced as a result of AOM may combine with reduced iron to form monosulfide, i.e., a precursor of pyrite. Subsequent reaction of the precursor with elemental sulfur or sulfides promotes the formation of pyrite. It is commonly the case that the pyrite crystal aggregation forms a framboidal shape, a so-called framboidal pyrite (for details see Chapter *Iron Sulfide Formation*). The sulfur isotopic composition of pyrite inherits the composition of the hydrogen sulfide source and indicates whether or not the hydrogen sulfide derived from bacterial sulfate reduction (Peckmann and Thiel, 2004).

Relationship to methane gas hydrate

Cold seeps are frequently associated with gas hydrate (Figure 4) where the environment has appropriate physical conditions for gas hydrate formation. The main component of the gas hydrate is methane but carbon dioxide, ethane, and other gaseous molecules are also present. Gas hydrates form in low temperature – high pressure environments where the appropriate concentrations of methane exist (Zhang, 2003). Such environments are usually distributed in the deep sea around continental margins and in permafrost areas on land. The hydrate is one of the largest methane reservoirs in the world. It has been estimated that more than 2,100 Gt of methane are stored in gas hydrates.

Formation of a mass of methane gas hydrate usually occurs within sediments whereas methane rapidly escapes and does not readily accumulate in water columns. If a substantial amount of methane, e.g., bubbly methane gas, is released into a water column, gas hydrate may form as a thin shell on the surface of a gas bubble (Figure 3).

The depth limit of gas hydrate formation and occurrence in the sediments is usually determined by the local geothermal gradient. The gas hydrate itself may act as an impermeable barrier within the sediment. In this case, the methane gas, which has migrated from the deep subsurface, is trapped and accumulates beneath the gas hydrate layer.

The importance of the gas hydrate for cold seeps is that (1) pore water surrounding the methane gas hydrate has an oversaturated level of methane, and (2) the rapid dissociation of methane gas hydrate may result in an episodic increase of cold seeps and sometimes an eruption of methane. When methane-undersaturated water penetrates the sediment and comes into proximity with the gas hydrate, the gas hydrate dissociates so as to create a physical equilibrium between the pore water and the gas hydrate. When the pore water, after taking up a substantial amount of methane, migrates further upward, a continuous methane supply is established between the methane gas hydrate reservoir and the sea floor.

Episodic emission of methane because of the dissociation of methane gas hydrate occurs, for example, in cases where the sea level decreases at the beginning of a glacial period or increasing sea water temperature because of global warming (e.g., Judd et al., 2002). The dissociation of gas hydrates may cause instability of the sea floor inducing landslides (Buffett, 2000). Such an underwater landslide results in additional lowering of pressure and may produce further dissociation of gas hydrate. It should be noted that the meaning of the existence of methane gas hydrate is that the area has large potential for the generation and/or accumulation of methane.

Because the density of gas hydrate is lower than that of sea water, the gas hydrate itself tends to rise upwards. Thus, an insufficient mixture of sediment in the gas hydrate and/or insufficient loading by overlain sediments causes the release of a mass of gas hydrate into a water column.

Ecosystem established at cold seeps – chemosynthesis-based ecosystems

Cold seeps can be considered as chemosynthesis-based ecosystems that support a large amount of life in deep seas (Figures 2 and 7; Sibuet and Olu, 1998). The main primary producers of the ecosystem found in cold seeps are chemoautotrophic microbes, such as sulfur-oxidizing bacteria. For the sulfur-oxidizing bacteria, hydrogen sulfide has the role of an electron acceptor, oxygen that of an electron donor, and carbon dioxide that of a carbon source. Such microbes that metabolize via the chemical reaction of inorganic compounds with an inorganic carbon source are called chemolithoautotrophs. An ecosystem based on chemoautotrophy is called a chemosynthesis-based ecosystem. This kind of ecosystem is a counterpart to the photosynthetic ecosystem found on the surface of the Earth. Chemosynthetic ecosystems establish themselves especially in areas where light does not penetrate such as the

Cold Seeps, Figure 7 Chemosynthesis-based community composed of a dense accumulation of *Bathymodiolus* (mytilid bivalves) from Kuroshima Knoll, off Okinawa, southwest of Japan. (by courtesy of the Japan Agency for Marine-Earth Science and Technology).

deep sea and the subsurface below the sea floor. Within these settings, chemosynthesis-based ecosystems particularly flourish at cold seeps and hydrothermal vents because these are environments where large amounts of reduced compounds encounter oxic waters.

With chemosynthetic microbes as a basis, heterotrophic microbes and animals flourish in cold seeps as members of the chemosynthetic ecosystem. In order to flourish in a oxygen-poor cold seep environment which is instead rich in toxic substances such as hydrogen sulfide, the animals found there often have a detoxification system (Felbeck et al., 1985). Most animals living in cold seeps house chemosynthetic bacteria, such as sulfur-oxidizing bacteria and methane-oxidizing bacteria, and obtain organic matter from those symbionts. These symbiotic chemosynthetic bacteria are called as chemosymbiotic bacteria. The animals living in cold seeps are generally endemic at a higher taxon level and diverge from the animals belonging to photosynthetic ecosystems. Major animals living in a cold seep environment are vesicomyid, mytilid, thyasirid, lucinid, and solemyid bivalves, provannid, acmaeid and neomphalid gastropods, and vestimentiferan tube worms. Crabs, sea urchins, sponges, and barnacles are occasionally found as minor faunal elements. Nectobenthic animals, i.e., animals that can live near the sea floor, such as hydrothermal vent shrimps, are relatively fewer in number at cold seeps than in hydrothermal vent fields. This is because the reduced compounds, their energy source, are often consumed already within the sediments, and only occasionally appear above the sea floor. In contrast, infaunal animals, i.e., animals that live in the sediment, are more abundant in cold seeps than in hydrothermal vents, because the cold seeps are usually covered by rich soft sediments whereas fresh

(recently formed) hard igneous rocks are exposed at hydrothermal vent fields.

The biotic composition of cold seeps is controlled by physicochemical factors including the quantity of reduced compounds such as methane and hydrogen sulfides. One good example of the biotic elements controlled by methane accumulations is seen at Hydrate Ridge (Cascadia Margin, off Oregon). *Beggiatoa* (sulfur-oxidizing bacteria) mats, *Calyptogena* (vesicomyid bivalve), and *Acharax* (solemyid bivalve) all flourish in this cold seep area in a zoned distribution. A large concentration of hydrogen sulfide was detected in the *Beggiatoa* zone, decreasing toward the *Acharax* zone through the *Calyptogena* zone (Sahling et al., 2002). A similar regulation of distribution caused by the concentration of hydrogen sulfide occurred at the species level. Two species of *Calyptogena* (bivalve), *C. kilmeri* and *C. pacifica*, coexisted in a cold seep but they were roughly segregated. The *C. kilmeri* lived where there was a much higher concentration of hydrogen sulfide and the other lived where the concentration of hydrogen sulfide was much lower (Barry et al., 1997).

The biotic component that lives in cold seep environments looks similar to those found in other reduced environments such as hydrothermal vents, sunken vertebrate carcasses, and driftwood (see Chapter *Whale and Wood Falls*). Actually, the components are mostly the same at a higher taxonomic level (i.e., genus or family level), although they are restricted to living in a single type of habitat at the species level (Peck et al., 1997), except for vertebrate carcasses (Smith and Baco, 2003). Twenty species found in a cold seep environment also live on/around vertebrate carcasses. Thus, vertebrate carcasses may play a role as a dispersal stepping stone prior to living in a cold seep at least for some species. It is generally thought that the macro organisms in hydrothermal vent environments have evolved from cold seep species (Hecker, 1985; McLean 1985; Craddock et al., 1995). In addition, molecular data indicate that mytilid bivalves living in a cold seep environment adapt to such a reduced environment via whale carcasses as an evolutionary stepping stone (Distel et al., 2000; Smith and Baco, 2003).

Ancient cold seeps

Recognition of ancient cold seeps

Numerous ancient cold seeps dating from various ages have been found in a variety of tectonic settings (Figures 1 and 8; see review in Campbell, 2006). The identification of ancient cold seeps depends on revealing features which indicate the presence of methane and other hydrocarbons which escaped from the sea floor. In order to make these features evident, a comprehensive approach based on geological, geochemical, and paleontological techniques is a primary requirement.

It is well known that carbonate minerals are forming in modern cold seep environments as a result of increased alkalinity due to AOM (Ritger et al., 1987; Aharon,

Cold Seeps, Figure 8 Late Cretaceous cold seep deposit (*above*) and dense accumulation of lucinid bivalves associated with the carbonate (*below*) from South Dakota, USA. The carbonate rock was induced by anaerobic oxidation of methane at a late Cretaceous active cold seep in the Western Interior Seaway, located in the eastern part of what is today the Rocky Mountains in northwestern America.

2000). Methane-derived carbonates are potentially imprinted with environmental information concerning the location where they were formed. Shapes, textures, and imprinted chemical signatures of modern cold seep

deposits can be seen as a good analog facilitating the recognition of ancient cold seeps. A conduit pipe such as a carbonate chimney (Takeuchi et al., 2007), although they are generally formed under the sea floor in contrast to chimneys at hydrothermal vents, is a good example indicating the route of fluid. Cold seep carbonates often have chaotic fractured structures. The fracture is usually ductile and/or accompanied by brittle sediment deformations. The deformations are probably due to active fluid venting. Microbially induced carbonate cements, e.g., clotted fabrics and isopachous fibrous cements, are frequently found in the carbonate. The influence of methane and microbial activity can be detected by further biogeochemical analysis (Peckmann and Thiel, 2004).

The carbon isotopic compositions of the carbonate reflect the values of the carbon source. Methane, the main gaseous component of cold seeps, generally shows negative carbon isotopic compositions in the case of thermogenic and biogenic methane (see above). The carbon isotopic compositions of thermogenic and biogenic methane commonly range from -30 to -50‰ and -50 to -80‰ (vs. PDB), respectively, and are thus distinguished from other carbon sources in the marine environment. These values will be imprinted at roughly the same level in the carbon isotopic compositions of the methane-derived carbonate. Considering that the $\delta^{13}\text{C}$ -values of carbonate are often somewhat higher than the values of the source methane because of the admixture of other carbon sources (Peckmann and Thiel, 2004), values ca. lower than -30‰ (vs. PDB) suggest that a major portion of the carbonate carbon is derived from methane.

Lipid biomarkers provide information on ancient microbial activities. It has been revealed that AOM is mediated by microbial consortia composed of archaea and sulfate-reducing bacteria (Orphan et al., 2002). Cell membrane lipids produced by those microbes have a strong propensity to be preserved in sediments (Peckmann and Thiel, 2004). Analyzing the carbon isotopic composition of each of these biomarkers (see entry *Biomarkers (Organic, Compound-Specific Isotopes)*) tells us whether or not the microbes used methane as the carbon source for their biosynthesis. The carbon isotopic compositions of lipids derived from methanotrophic microbes sometimes reach as low as -120‰ or even lower. On the basis of this information, the presence of isotopically depleted lipid biomarkers derived from archaea will be a good indicator for the occurrence of AOM (Elvert et al., 2005).

Oldest cold seep

Ancient cold seeps with chemosymbiotic macrofossils have been traced back to at least Silurian (Barbieri et al., 2004). As it is difficult to find and recognize ancient cold seeps without macrofossils, there is practically no record of older cold seeps. However, a possible cold seep occurring after the severe glacial period around 600 Ma, i.e., the period known as “Snowball Earth,” has recently been

proposed. The evidence for a cold seep related to the dissociation of methane gas hydrate is the strongly negative carbon isotopic composition of the “cap carbonate” from south China (Jiang et al., 2003). However, cap carbonates on a glacial deposit formed around 600 Ma are widely distributed throughout the world. If all the cap carbonates were formed under the influence of dissociating methane gas hydrate, numerous cold seeps would have appeared at that time. It is easy to imagine that widespread cold seeps existed in the Precambrian because biogenic methane already existed at 3.5 Ga (Ueno et al., 2006). The apparent lack of cold seeps in the Precambrian, apart from the cap carbonate, is probably due to their having been overlooked because of a lack of associated macro fossils.

Changes in cold seeps through time

The number of cold seeps varies through the Phanerozoic. In the Paleozoic, there are only five ancient cold seep localities. In spite of the fact that a stratigraphic change in carbon isotope ratios shows a global negative shift at the Permian/Triassic boundary, probably caused by the release of a large amount of methane into the ocean and the atmosphere, probably from methane gas hydrate, there are no records of ancient cold seeps from the Permian and Triassic. However, the number of records of ancient cold seeps in post-Triassic marine sediments has increased. More than 15 localities have been found in the Mesozoic and in an abundance of localities, more than a dozen, from the Cenozoic (Campbell, 2006). The cause of the drastic increase in cold seeps since the late Mesozoic might be due to an increase of organic flux into sediments resulting from increasing planktonic productivity and diversity during the Mesozoic Era (Tappan and Loeblich, 1973; COSOD II, 1987) leading to increasing generation of methane in marine sediments.

The biotic components of cold seeps changed through the Phanerozoic (Campbell and Bottjer, 1995; Little and Vrijenhoek, 2003). Mollusks are the most dominant organism in modern cold seeps, despite the dominance of brachiopods in the Paleozoic and mid-Mesozoic. The brachiopods were replaced by mollusks, mainly by bivalves, in the late Mesozoic (Campbell and Bottjer, 1995; Kiel and Peckmann, 2008). The last abundant occurrence of brachiopods in cold seeps is found from the Campanian, late Cretaceous (ca. 80 Ma), from the Omagari, Hokkaido, Japan (Hikida et al., 2003; Kaim et al., 2010). Vesicomyid and bathymodiolian bivalves, which flourished in modern cold seeps, entered the cold seep environment during the Eocene (Ca. 40 Ma; Kiel, 2006; Amano and Kiel, 2007; Amano et al., 2008). It should be noted that the fossil record of vesicomyid bivalves has recently been reexamined and its origin changed from Cretaceous to Eocene (Amano and Kiel, 2007; Amano et al., 2008; Kiel et al., 2008). Most living molluscan genera which lived in ancient cold seeps originated in the late Mesozoic to Paleogene (see basic data in Kiel and Little, 2006 and updated data in Amano et al.,

2007; Jenkins et al., 2007; Campbell et al., 2008; Kaim et al., 2008; Kiel et al., 2008; Kaim et al., 2009).

Impact on climate change

Judd et al. (2002), indicate that the input of greenhouse gases from the sea floor into the world's oceanic and atmospheric systems may be an important component of the atmospheric carbon budget, because the greenhouse potential of methane is more than 20 times that of carbon dioxide. A catastrophic release of methane may therefore produce global climate changes. Such an event due to the rapid escape of methane into the atmosphere happened at the Paleocene–Eocene boundary (ca. 55.5 Ma). At that time, the rapid dissociation of methane hydrate and subsequent release of methane into the atmosphere resulted in global warming and an increase of 6°C in the sea surface temperature (Dickens et al., 1995). A similar methane release outburst is thought to have occurred at the end-Permian forming one of the biggest known biodiversity crises (see entry *Critical Intervals in Earth History*) (Ryskin, 2003; Retallack and Krull, 2006). Kennet et al. (2002) proposed that the periodic glacial-interglacial cycle during Quaternary was controlled by the decomposition of methane gas hydrate and the subsequent release of methane gas into the atmosphere. Evidence of these methane releases comes mostly from carbon isotopic anomalies which were recorded in carbonate and organic material. The release of isotopically depleted biogenic methane induces negative carbon isotope excursions because of the transfer of ¹³C-depleted carbon from methane to carbon dioxide.

Summary

Cold seeps have been the object of considerable attention because of their role as a connecting pipe between the lithosphere, hydrosphere, and biosphere on the Earth. Reduced compounds contained in cold seep fluid result in substantial biogeochemical reactions. The establishment of a cold seep requires specific geological and biological background conditions, such as tectonic stress to make a route for the fluid, sedimentary organic matter supply to provide a source of methane and other hydrocarbons, microbial and/or geothermal activities to form the hydrocarbons, and microbial activities accounting for the oxidation of reduced compounds. Revealing the processes and mechanisms has largely progressed during the last 2 decades. For example, it was revealed at the time of the transition from the twentieth to the twenty-first century that anaerobic methane-oxidizing archaea and sulfate-reducing bacteria are responsible for the anaerobic oxidation of methane. However, there are still many questions about cold seeps that remain unresolved, e.g., the long-term behavior of cold seeps, response to climate change and details of various biological processes and mechanisms. Gaining an understanding of cold seeps is a primary requirement because a cold seep provides a condensed version of

geobiochemical processes related to methane. Thus, the knowledge that we can obtain from the research on cold seep may help us to understand a much wider range of geobiological phenomena taking place on Earth.

Furthermore, methane, the main component contained in cold seep fluids, has a potentially large effect on global warming. It is evident from several geological records through the Phanerozoic that dissociation of methane gas hydrate has drastic effects in terms of global climate change. Methane is also attractive to human beings because of its large potential as a future energy source. In fact, the methane amount stored in gas hydrate beneath the sea floor and permafrost is more than 2,100 Gt. However, as noted above, methane has a tremendous potential to bring about global climate change on the Earth. Thus, any form of intervention in the natural gases in marine sediments should be carefully carried out on the basis of sufficient knowledge of what will happen when the methane is released from the sea floor. Adopting this stance implies a very strong requirement to reveal the entire range of processes and mechanisms within a cold seep.

COMETS

Comets are primitive conglomerates of the solar system containing a mixture of frozen gases, refractory grains, and carbonaceous particles rich in biogenic elements (Llorca, 2005). The great variety of organic molecules carried by comets could have played a major role in prebiotic processes prior to the appearance of microorganisms. Please refer to entries “*Astrobiology*,” “*Asteroid and Comet Impacts*,” “*Meteoritics*,” and “*Origin of Life*.”

COPPER

Stephan M. Kraemer
 University of Vienna, Vienna, Austria

Definition

Copper (Cu) is a transition metal that serves as an essential nutrient to eukaryotes and many prokaryotes due to its many functions in copper enzymes. At elevated concentrations, Cu is toxic and the many industrial uses of copper

and its release to the environment has resulted in Cu pollution in soils and surface waters.

Properties: Copper has two stable isotopes ^{63}Cu and ^{65}Cu with a natural abundance of 69.17 and 30.83, respectively, and a standard atomic weight of 63.546 (Coplen et al., 2002; Wieser, 2007). The copper concentration in the bulk continental crust, in the oceanic crust, and in soils is estimated to be 27 ppm (Rudnick and Gao, 2003), 78 ppm (Wedepohl and Hartmann, 1994), and 39 ppm (Han et al., 2002), respectively. The concentrations of copper in unpolluted seawater is typically around 0.3 ppb and in river water, 1.5 ppb (Gaillardet et al., 2003). The world average concentration of copper in rivers has been estimated as 23.6 nM Cu dissolved load and 100 ppm Cu suspended particulate load (Martin et al., 1993; Martin and Meybeck, 1979; Martin and Thomas, 1994). In natural systems, it occurs in the Cu(I) (cuprous) or Cu(II) (cupric) redox states and rarely as elemental copper. The standard redox potential of the aqueous Cu(I)/Cu(II) couple is at 0.34 V, but the actual redox potential depends strongly on its coordinative environment. This is exploited by organisms using Cu as reactive center of reductases with high redox potentials between +0.2 and +0.8 V.

Copper toxicity: Due to its toxicity to humans, the US-EPA maximum contaminant level goals and EU standards for copper in drinking water has been set at 1.3 (USEPA, 1991) and 2 mg/l (EU, 1998), respectively. Copper is also toxic to marine and terrestrial prokaryotic and eukaryotic organisms (Flemming and Trevors, 1989; Gledhill et al., 1997). Its toxicity derives from its redox reactions producing radical ions similar to Fenton chemistry causing oxidative stress. Phytochelatins (plants) and metallothioneins (animals, fungi) are intracellular metal binding proteins that play an important role in detoxification and homeostasis of Cu and other metal ions.

Copper as a nutrient: Copper-containing oxidoreductase enzymes are widespread among prokaryotic and eukaryotic organisms and mediate important biogeochemical processes, including nitrification, denitrification, and methane oxidation. Examples are particulate methane monooxygenase, ammonia monooxygenase, nitrite reductase, cytochrome *c* oxidase, and superoxide dismutase. It has been suggested that Cu-bearing reductases evolved only after the oxygenation of the Earth atmosphere, considering the low solubility of Cu in sulfidic environments and the high redox potential of organically bound Cu(I)/Cu(II) up to the limit of the stability field of water (Frausto da Silva and Williams, 2001). Copper is part of a metalloenzyme involved in the uptake of iron by diatoms so that a Cu/Fe co-limitation of primary productivity in the ocean is conceivable (Maldonado et al., 2006; Peers et al., 2005). Recently, it was discovered that some methanotrophic bacteria possess a high-affinity Cu uptake system involving methanobactin, a structurally distinct chromopeptide metallophore analogous to iron-specific siderophores (DiSpirito et al., 1998). This highlights the potential role of copper availability and copper uptake in regulating biogeochemical cycles.

CALCAREOUS ALGAE

The term “calcareous algae” refers to various kinds of benthic and planktonic algae whose thalli contain biochemically precipitated calcium carbonate (CaCO_3) as skeletal material (Wray, 1977; Braga and Riding, 2005). Precipitation of CaCO_3 (as calcite and/or aragonite) may occur within or on the algal bodies. The term may also include mechanically accreted deposits of calcium carbonate caused by algae, usually as an interaction of biological and physical processes. Calcareous algae are a highly artificial group that constitutes calcifying members of the Chlorophyta (green algae), Rhodophyta (red algae), and Phaeophyta (brown algae) and is sometimes also used for Cyanobacteria. At present, calcareous algae are one of the most important reef builders (see “[Carbonate Environments](#)”). For a detailed reading, please refer to “[Algae \(Eukaryotic\)](#).”

CALCIFIED CYANOBACTERIA

Robert Riding
University of Tennessee, Knoxville, TN, USA

Definition

Cyanobacteria are alga-like bacteria that can perform oxygenic photosynthesis and nitrogen fixation (Whitton and Potts, 2000; Herrero and Flores, 2008). They have a long history and are diverse and widespread in marine, freshwater, and terrestrial environments at the present-day, where they are key primary producers in both microbial mat and planktic ecosystems. As the initiators of plastids, they have played a fundamental role in algal and plant evolution (Raven, 2002). Cyanobacteria occupy benthic substrates and can also drift in the water column. Their photosynthetic uptake of inorganic carbon can stimulate CaCO_3 precipitation. This calcification can produce filamentous microfossils in benthic mats that are preserved as stromatolites and thrombolites, and can also cause water column precipitation of carbonate mud that settles to lake and sea floors.

Introduction

However, cyanobacterial calcification is not obligatory and is directly dependent on environmental conditions. This accounts for apparent discrepancies between the geological ranges of organic-walled and calcified cyanobacterial fossils. Calcified cyanobacteria have not been recognized in marine sediments older than ~1200 Ma ago (Kah and Riding, 2007), whereas there is evidence that cyanobacteria appeared in the late Archaean or Palaeoproterozoic, in the range ~2900–2150 Ma ago (Cavalier-Smith et al., 2006; Hofmann, 1976). This mid-Proterozoic appearance of sheath-calcified cyanobacteria is thought to reflect the development of CO_2 -concentrating

mechanisms (CCMs) as atmospheric CO₂ levels declined (Riding, 2006). Calcified cyanobacterial fossils remained conspicuous components of marine stromatolites and thrombolites through much of the Neoproterozoic, Palaeozoic, and Mesozoic, but became vanishingly scarce in the Cenozoic, including present-day seas (Riding, 1982), probably due to decline in seawater saturation for CaCO₃ minerals (Riding, 1993, p. 514; 2000, p. 200; Kempe and Kazmierczak, 1994). Cyanobacterial calcification is thus a good example of “induced,” as opposed to “controlled” biocalcification. Its close environmental dependence can be used to interpret changes in past conditions such as carbonate saturation state and the availability of inorganic carbon for photosynthesis. In addition to their sedimentological importance, calcified cyanobacteria can therefore assist in the reconstruction of seawater chemistry and atmospheric composition over long geological time scales.

Controls on calcification

The ability of cyanobacteria to grow and reproduce whether they are calcified or uncalcified illustrates the non-obligate nature of their calcification (Pentecost and Riding, 1986). Two factors that directly influence cyanobacterial calcification are the saturation state of ambient waters and the mechanism of photosynthetic uptake of inorganic carbon (Riding, 2006).

Carbonate saturation state: Cyanobacterial calcification requires waters in which CaCO₃ precipitation is thermodynamically favored (Pentecost, 1981; Kempe and Kazmierczak, 1994; Merz-Preiß and Riding, 1999). It has been very common in marine environments at times since the Neoproterozoic, but these episodes are markedly episodic and can be interspersed by long periods when cyanobacterial calcification is scarce (Riding, 1992). Cyanobacterial sheath calcification has not been confidently recognized in present-day marine environments, and is rare to absent throughout the Cenozoic (Riding, 1982; Arp et al., 2001). In contrast, cyanobacterial calcification is locally well-developed in present-day calcareous streams and lakes, and is often significantly involved in the formation of tufa and oncoids (Golubic, 1973; Pedley, 1990; Pentecost, 2005). In streams, calcification reflects increased saturation state that results from warming and degassing of spring waters, especially in turbulent zones, together with the stimulus of photosynthetic carbon removal (Merz-Preiß and Riding, 1999; Bissett et al., 2008). In lakes, precipitation is stimulated by seasonal warming as well as the activity of phytoplankton blooms that include cyanobacteria (Kelts et al., 1978; Thompson and Ferris, 1990). These present-day environments are vulnerable to pollutants such as agricultural fertilizers. Cyanobacterial calcification has declined over the past century in temperate climate hardwater streams and lakes of Europe and North America, largely in response to these anthropogenic changes (Pentecost, 2005, pp. 283–287),

among which phosphate inhibition of CaCO₃ precipitation (Raistrick, 1949) may be important (Hägele et al., 2006).

CO₂-concentrating mechanisms: Photosynthetic carbon uptake can directly influence cyanobacterial calcification. Diffusive entry of CO₂ into the cell may not significantly affect ambient pH, but active bicarbonate uptake increases pH near the cell (Miller and Colman, 1980) that promotes calcification (Thompson and Ferris, 1990). Bicarbonate (HCO₃[−]) is actively transported into the cell and intracellularly converted to CO₂ for photosynthesis. These processes lead to increased pH in the immediate vicinity of the cell. Where ambient waters are sufficiently saturated for CaCO₃ minerals then this localized pH increase can trigger the nucleation of CaCO₃ crystallites on or near the cell surface or in the enveloping mucilaginous sheath (Figures 1 and 2):

Active bicarbonate uptake and its conversion within the cell to CO₂ by carbonic anhydrase are adaptations to reduced availability of CO₂. They constitute CCMs (Kaplan and Reinhold, 1999). CCM induction can be triggered by localized carbon limitation, e.g., within microbial mats or phytoplankton blooms, and also by fall in global atmospheric CO₂ levels. Modeled estimates suggest that atmospheric CO₂ has fluctuated widely during the Phanerozoic, up to levels that are 25 or more times higher than present atmospheric level (PAL) (Berner and Kothavala, 2001). CCMs are well-developed in cyanobacteria (Kaplan et al., 1980; Giordano et al., 2005) and experiments suggest that they are induced when ambient CO₂ falls below a critical threshold that is roughly equivalent to 10 PAL (Badger et al., 2002). It therefore seems likely that CCM induction plays a significant role in cyanobacterial calcification (Thompson and Ferris, 1990; Merz, 1992), especially at times in the geological past when CO₂ levels have been below 10 PAL (Riding, 2006, p. 302).

Sites of calcification

Calcification in cyanobacteria is close, but external, to the cell. CaCO₃ crystals nucleate either within the protective mucilaginous sheath, or on or close to the cell surface (Thompson and Ferris, 1990; Merz, 1992). Sheath impregnation by crystallites (Figure 1) can produce coherent tubular and shrub-like calcified structures that preserve the sheath morphology and can be preserved as microfossils for hundreds of millions of years (Riding, 1991). In contrast, if isolated crystals form near the cell surface, they do not form a preservable shape but can be released as allochthonous particles (“whittings”) (Figure 2). These can accumulate as masses of micron-size carbonate mud sediment on lake and sea floors and can also survive as ancient geological deposits. However, they are not known to possess features that distinguish them as

Calcified Cyanobacteria, Figure 1 Model of in vivo sheath calcification in a filamentous cyanobacterium related to CO_2 -concentrating mechanism (CCM)-enhanced photosynthesis (based on information in Riding, 2006, Fig. 3). The CCMs involve active carbon transport into the cell and conversions that liberate OH^- ions. Calcification is stimulated by photosynthetic carbon uptake and OH^- release which elevates sheath pH. If ambient carbonate saturation is already elevated, with raised pH, extracellular HCO_3^- converts into CO_3^{2-} , further increasing saturation state that promotes CaCO_3 nucleation in the sheath.

Calcified Cyanobacteria, Figure 2 Model of in vivo sheath calcification in a picoplanktic coccoid cyanobacterium related to CCM-enhanced photosynthesis (based on information in Riding, 2006, Fig. 3). The CaCO_3 nucleation (blue diamonds) occurs on and near the cell surface. The crystals can ultimately be sedimented to the lake or sea floor as carbonate mud.

cyanobacterially induced precipitates, and cannot at present be differentiated from carbonate mud of other origins.

Sheath calcification: The protective mucilaginous sheath that envelops benthic calcified cyanobacteria provides a diffusion limited site that enhances the pH rise resulting from carbon uptake (Figures 3 and 4). The sheath is a structured form of EPS (Drews and Weckesser, 1982) providing support, stability, and protection against physical damage, dehydration, and grazers (Dudman, 1977). It can contain the pigment scytonemin that acts as a barrier to ultraviolet radiation (Garcia-Pichel and Castenholz, 1991; Proteau et al., 1993; Dillon and Castenholz, 1999), binds nutrients and metals (Yee et al., 2004), and facilitates gliding motility (Stal, 1995, p. 4; Hoiczky, 1998). Sheath calcification can be partial or complete, and can be limited to the sheath interior (sheath impregnation) or form an external crust (sheath encrustation) (Riding, 1977). For example, it can occur as isolated crystals (Pentecost, 1987, Fig. 1d), form a crystalline network (e.g., Friedmann, 1979, Fig. 9), or create a relatively solid tube of closely juxtaposed crystals (e.g., Couté and Bury, 1988, pl. 2).

Although saturation state with respect to carbonate minerals and CCM induction appear to be key controls on cyanobacterial sheath calcification over geological timescales (Riding, 2006), differences in degree of calcification between different species/strains of cyanobacteria in the same environment also indicate taxonomic specificity for calcification (Golubic, 1973; Merz, 1992; Défarge et al., 1994). Further research is required to elucidate the extent to which such specificity may reflect differences in sheath structure and sheath development, CCM induction, or other factors.

Calcified Cyanobacteria, Figure 3 *Girvanella*, calcified cyanobacterial sheath, early mid-Ordovician, Lunnan, Tarim, China. Width of view 1 mm. Thin-section courtesy Jia-Song Fan.

Calcified Cyanobacteria, Figure 4 Thin-section of present-day oncoid microfabric showing calcified shrub-like sheath surrounding space left by the strand of cells (trichome, arrowed). The cyanobacterium is thought to be the oscillatoriacean *Schizothrix calcicola*, and the calcified sheath closely resembles the microfossil *Angulocellularia* (also *Angusticellularia*), which is locally common in Cambro-Ordovician reefs (Riding and Voronova, 1982). Squaw Island, Canandaigua Lake, New York State, USA.

In addition to in vivo sheath calcification, postmortem sheath degradation by heterotrophic bacteria can result in partial external calcification (Chafetz and Buczynski, 1992), although in culture experiments this may in part be related to the growth medium used (Arp et al., 2002). This incomplete and irregular calcification of decomposing sheaths contrasts with sheath impregnation that produces well-defined tubiform fossils such as *Girvanella* in which wall-thickness remains constant in individual specimens (Riding, 1977, 2006).

Biogenic whiting precipitation: In contrast with relatively large and distinct calcified fossils, such as *Girvanella*, that result from sheath calcification, CaCO_3 precipitates associated with coccoid cyanobacterial blooms are most noticeable as “whittings”. These are ephemeral milk-white patches in freshwater calcareous lakes and shallow tropical seas formed by dense masses of suspended small CaCO_3 crystals (Cloud, 1962). Whiting is a descriptive term, and all whittings are not necessarily biogenic. In addition to the triggering effect of phytoplankton photosynthesis, they could reflect essentially abiogenic CaCO_3 crystal nucleation in the water column, and also – in very shallow water – bottom mud re-suspended by currents or fish (Shinn et al., 1989).

Biogenic cyanobacterial whittings are documented by studies of seasonal blooms of unicellular picoplanktic (cell size in range 0.2–2 μm) cyanobacteria, such as *Synechococcus*. These benefit from efficient CCMs (Badger and Price, 2003) where dissolved inorganic carbon (DIC) availability is limited, as under bloom conditions (Rost et al., 2003). Together with diatoms and other planktic algae, *Synechococcus* is implicated in stimulating biogenic whiting precipitation in present-day freshwater calcareous oligotrophic lakes (Thompson and Ferris, 1990; Dittrich et al., 2004; Lee et al., 2004). Since a sheath is lacking in picoplankton such as *Synechococcus*, calcification is instead localized on a paracrystalline surface layer that provides a binding site (Thompson, 2000, p. 253). This surface layer can be shed, producing biogenic whiting crystals that are deposited from suspension, either individually or as poorly structured aggregates along with organic cells, on lake beds.

In addition to lakes, picoplanktic cyanobacteria are widespread in the open ocean and in nearshore marine environments. They form blooms in Florida Bay, and marine strains of *Synechococcus* calcify under experimental conditions (Lee et al., 2004). There has been much debate concerning whether marine whittings in shallow tropical seas, such as the Bahama Banks, have a similar origin to those in temperate calcareous lakes, and could therefore potentially account for abundant lime mud production on ancient carbonate platforms. If marine whittings on the Bahama Banks are water column precipitates, then they would be important sources of carbonate mud and could be triggered by planktic cyanobacteria (Robbins and Blackwelder, 1992; Robbins et al., 1997). However, CaCO_3 precipitation in freshwater lakes is favored by low pH buffering, whereas in present-day seawater buffering limits pH fluctuation, thereby reducing the response to photosynthetic removal of CO_2 and HCO_3^- . Several studies have suggested that Great Bahama Bank whittings are not due to water column precipitation (Broecker and Takahashi, 1966; Morse et al., 1984; Broecker et al., 2000). For example, whiting CaCO_3 has a $^{14}\text{C}/\text{C}$ ratio that differs from that of inorganic carbon in the whiting water, but is similar to that of the seafloor sediment. In addition, the saturation state of Bahama Bank waters appears to be too low for pseudohomogeneous precipitation of CaCO_3 .

(Broecker et al., 2001, p. 591; Morse et al., 2003). Broecker et al. (2000) concluded that resuspension of sediment is the dominant process involved in marine whittings on the Bahama Banks. Further work is required to resolve this question, but present-day seawater saturation state in general may be too low to permit CaCO_3 nucleation even within blooms of picoplankton that are operating CCMs.

Nonetheless, biogenic whittings may have occurred under different conditions of seawater chemistry in the geological past, and could therefore have been important sources of fine-grained carbonate. Within plankton blooms, photosynthetic uptake can significantly deplete pCO_2 (Riebesell et al., 1993; Rost et al., 2003), and it is likely that selective pressure for picoplankton to induce CCMs first developed under bloom conditions.

Fossil calcified cyanobacteria

Calcified cyanobacterial fossils have long been noticed in limestones, although they have often been confused with other organisms. Sheath calcified cyanobacteria are morphologically simple fossils, mainly with the appearance of shrub-like dendritic masses (Figure 4) and tangled or erect, sometimes radially arranged, tubes (Figure 3). Densely micritic branched filaments such as *Epiphyton*, and chambered clusters such as *Renalcis* have also often been regarded as possible calcified cyanobacteria. At the same time, because of their general lack of distinguishing features, many of these fossils have often also been compared with calcified green and red algae, and also with foraminifers and sponges. For example, when Nicholson and Etheridge (1878) named *Girvanella* they compared it with foraminifers, and it has subsequently variously been regarded as a calcareous sponge (Seely, 1885), green alga (Rothpletz, 1891), and red alga (Korde, 1973). Bornemann (1886) recognized its cyanobacterial nature, and Pollock (1918) identified it as a calcified sheath. Individual calcified cyanobacteria are normally microscopic, but they commonly form much larger aggregates that are significant components of stromatolites, oncoids, thrombolites, dendrolites, reef crusts, and freshwater tufa deposits that range up to decametric in size.

Three main morphological groups can be distinguished (Riding, 1991): tubes, dendritic shrubs and filaments, and hollow chambers.

Tubes: *Girvanella*, originally described from the Middle Ordovician of Scotland, is very simple: unbranched, often irregularly tangled, tubular filaments of uniform diameter, usually <50 microns, and a thin wall of even thickness (Figure 3). Similar tubes, but often organized into cable-like strands, include *Batinivia*, *Botominella*, *Cladogirvanella*, *Razumovskia*, and *Subtifloria*. *Obruchevella* is coiled. *Ortonella* was described from the Mississippian of England (Garwood, 1914) where it forms oncoids (spherical stromatolite nodules) and stromatolitic crusts. It consists of tubes similar in size to those of *Girvanella*, but distinguished by being erect and branched. Somewhat similar forms include *Bajanophyton*,

Bija, *Botomaella*, *Cayeuxia*, and *Hedstroemia*. Pia (1927, pp. 36–40) recognized that very small tubiform fossils such as *Girvanella* and *Ortonella* were cyanobacteria when he placed them in a new group, the Porostromata.

Dendritic shrubs and filaments: *Angusticellularia* (also named *Angulocellularia*) described from the Cambrian of Siberia by Vologdin (1962) is a submillimetric vertically orientated and irregularly dendritic shrub-like mass of dense micrite (Figure 4). In contrast, narrow branched micritic filaments, usually not tubiform but in some cases with light-colored transverse bands, comprise a group that includes *Epiphyton*, originally described from the Cambrian of Sardinia by Bornemann (1886), and among others, *Epiphytonoides*, *Gordonophyton*, and *Tubomorphophyton*.

Hollow chambers: *Renalcis*, described from the Cambrian of southern Siberia by Vologdin (1932), is a hollow thick-walled chambered microfossil that typically forms irregular submillimetric clusters. Broadly similar fossils, such as *Izhella* and *Shuguria*, are distinguished by wall thickness and number of chambers. Some form millimetric dendritic growths. *Chabakovia* filaments consist of thin-walled chambers. In contrast, *Gemma* and *Tarthina* have few chambers with very thick walls.

There is considerable mingling of characters among some of these generally simply organized fossils that can make them difficult to distinguish within these broad groups (Pratt, 1984; Riding and Voronova, 1985; Woo et al., 2008). Dense filaments and chambered forms are much more problematic, whereas tubiform and shrub-like forms can often be compared with present-day sheath calcified cyanobacteria. These include sedimentologically important Cambrian and late Devonian fossils such as *Epiphyton* and *Renalcis* that have some resemblances to cyanobacteria but are not identical to modern examples, and are generally referred to as calcimicrobes. Some *Epiphyton* closely resemble red algae (Luchinina and Terleev, 2008).

Proterozoic record and secular controls

The possibilities that marine carbonate saturation state and changes in atmospheric CO_2 level could be reflected in the geological record of cyanobacterial calcified microfossils and carbonate mud (Riding, 2006, p. 309) focuses attention on the mid-Proterozoic interval when calcified sheaths first appeared (Kah and Riding, 2007) and carbonate mud became abundant (Sherman et al., 2000, p. 290) (Figure 5).

CCM induction

Badger et al. (2002) suggested that cyanobacterial CCMs developed in the late Palaeozoic as CO_2 declined and O_2 increased. However, both modeling and palaeosol proxies (Kasting, 1987; Sheldon, 2006) suggest that similar decline in CO_2 occurred in the mid-Proterozoic. It can therefore be suggested that the Mesoproterozoic appearance of calcified sheath microfossils reflects development of CCMs as CO_2 fell below a critical threshold that may

Calcified Cyanobacteria, Figure 5 Increase in marine carbonate mud accumulation ~1400–1300 Ma ago (Sherman et al., 2000) and first appearance of sheath-calcified cyanobacteria ~1200 Ma ago (Kah and Riding, 2007) compared with decline in estimated atmospheric CO₂ values. It is suggested that decline in CO₂ to ~10× present atmospheric level favored development of CCMs that promoted cyanobacterial sheath calcification and whiting production (Riding, 2006). Incorporation of calcified filaments in microbial carbonates gave rise to calcified microbe thrombolites and dendrolites. Inferred Proterozoic CO₂ trend based on Sheldon (2006), Kah and Riding (2007), Hyde et al. (2000), and Ridgwell et al. (2003). Phanerozoic CO₂ trend from Berner and Kothavala (2001, Fig. 13). Threshold for CCMs based on Badger et al. (2002). Decline in CO₂ level below 10× present-level was repeated ~350 Ma ago and coincides with marked Devonian-Mississippian increase in calcified cyanobacteria (see Arp et al., 2001, Figs. 3d and 8b).

have been ~10× PAL (Badger et al., 2002; Riding, 2006; Kah and Riding, 2007). Under high early Proterozoic CO₂ levels, cyanobacterial photosynthesis may have relied on CO₂ diffusion that may not have significantly altered pH near the cell surface. Falling CO₂ levels would have encouraged active carbon uptake to maintain photosynthesis and this, in turn, promoted calcification (Figures 1 and 5).

Carbonate mud: Carbonate mud appears to have been scarce in the late Archaean (Sumner and Grotzinger, 2004), but it increased in abundance during the Proterozoic (Kah and Grotzinger, 1992) and was widespread in the Neoproterozoic (Herrington and Fairchild, 1989). Much of it is thought to have been produced by whittings stimulated by phytoplankton photosynthesis (Grotzinger, 1989, 1990). A significant increase in carbonate mud occurred ~1400–1300 Ma ago (Sherman et al., 2000, p. 290), prior to the appearance of sheath calcification (Kah and Riding, 2007). This “water column factory” transformed carbonate platform sedimentation by creating extensive micrite-rich subtidal deposits (Sherman et al., 2000, p. 290). The timing of this increase in carbonate mud therefore broadly coincided with the first appearance of *Girvanella*-like and other sheath-calcified fossils (see below), and may be linked to CCM development in cyanobacteria, but in this case to planktic forms, possibly similar to present-day *Synechococcus* (Riding, 2006). Muddy carbonate platforms were the deposits in which distinctive molar tooth facies developed (James et al.,

1998; Sherman et al., 2000, p. 290). It can therefore be speculated that mid-late Proterozoic increase in micrites and molar tooth facies, together with *Girvanella* and thrombolites, all reflect decline in atmospheric CO₂ that stimulated CCM induction and calcification in cyanobacteria (Riding, 2006) (Figure 5).

Cyanobacterial sheath calcification: The first appearance of calcified cyanobacteria in the mid-Proterozoic – interpreted to reflect the first development of CCMs in photosynthetic organisms (Riding, 2006) – marked a radical change from stromatolitic to thrombolitic fabrics. Mesoproterozoic examples reported from the ~1200 Ma Society Cliffs Fm are currently the oldest known *Girvanella*-like calcified filaments, and are associated with micritic bush-like structures also interpreted as calcified cyanobacteria (Kah and Riding, 2007). The presence of filamentous fabrics had long been recognized in late Proterozoic and early Palaeozoic stromatolites. Microstructure with filament moulds was termed Canaliphorida and Filiformita by Komar (1976, 1989, see Bertrand-Sarfati et al., 1994, p. 182, Fig. 18). Aitken (1989, pp. 15–16) described “dendriform” and “lamelliform elements” as important components of Little Dal reefs in the Mackenzie Mountains. He regarded both as stromatolites with “unusual” or “unique” characteristics: thin-walled tubes and *Renalcis*-like objects in dendriform element, and a reticulate “ladder-rung” arrangement that “may be formed by a meshwork of tubes” in lamelliform element. He remarked that these fabrics “are not typically

stromatolitic” and that “sediment trapping may not have been the dominant process in their formation” (p. 15). Dendriiform and lamelliform elements look quite similar in two of his illustrations (Figs. 10 and 13). Subsequently, Turner et al. (1993, 2000a, Fig. 10b, 2000b) compared the tubules with *Girvanella* and noted that the lamelliform fabric consists of alternating dark layers of “calcimicrobial filaments” and lighter “more cement-rich” areas. Little Dal “hollow tubules with micritic walls” are figured by Batten et al. (2004, Fig. 9b). Knoll and Semikhatov (1998, p. 410, Figs. 3 and 4) described well-preserved “filmy or platy” microstructure in early Neoproterozoic *Baicalia lacera* stromatolites from the Chernaya Rechka Fm, Igarka, Siberia. They found it to be associated with “a distinctly filamentous microstructure” in which “laminae comprising densely interwoven to scattered, vertically, or subhorizontally oriented filaments are interspersed with layers of spongy or dense microspar.” They interpreted the 8–10 μm tubes as “sheaths of LPP-type (*Lyngbya*, *Phormidium*, *Plectonema*) cyanobacteria and preserved as drusy microspar encrustations” (Knoll and Semikhatov, 1998, p. 411). Similar *Baicalia lacera* fabrics in the $\sim 1\text{Ga}$ Burovaya Formation of west-central Siberia locally contain calcified tubes resembling *Siphonophycus* (Petrov and Semikhatov, 2001, p. 270). The lamelliform element shown by Turner et al. (2000a, Fig. 10b) resembles the distinctive “filmy” microstructure of similar age *Baicalia lacera* (Petrov and Semikhatov, 2001, Figs. 5b and 6a) which also has steeply dipping laminae and, as noted above, quite possibly filamentous microstructure too. In these examples, layers of filamentous fabric are generally interleaved with lighter, sparry, layers. If the sparry layers were lacking, the deposit would be indistinguishable from “skeletal stromatolite” (Riding, 1977) and “porostromate stromatolite” (Monty, 1981). In addition to the Little Dal and Chernaya Rechka examples, calcified filaments reminiscent of *Girvanella* are relatively widespread elsewhere

in the Neoproterozoic, e.g., in the ~ 750 – 700 Ma Draken Fm, ~ 725 – 675 Ma Svanbergfjellet Fm, and $\sim 700\text{ Ma}$ Upper Eleonore Bay Supergroup, Greenland (refs in Knoll and Semikhatov, 1998, p. 413). Throughout the Neoproterozoic, these thrombolites with calcified microbial fabrics (Kennard and James, 1986) are intimately associated with stromatolites but typically occur in deeper subtidal environments (Aitken, 1967).

Marine carbonate saturation

Inception of cyanobacterial calcification would have required overall seawater carbonate saturation to be relatively high. Grotzinger (1990) has argued that seawater saturation state progressively reduced during the Proterozoic and that this could account for concomitant decline in stromatolite abundance. Nonetheless, the widespread continued development of microbial carbonates into the Neoproterozoic, together with calcified sheaths themselves, indicates that saturation state was not low. This may have changed during widespread glaciations that occurred in the late Proterozoic ~ 700 – 570 Ma ago (Walter et al., 2000). Sheath-calcified cyanobacteria appear to have been scarce during “Snowball” glaciations. Lower temperature and $p\text{CO}_2$ levels would have decreased seawater saturation state, hindering microbial calcification generally. Shields (2002) attributed decline in Molar Tooth facies $\sim 750\text{ Ma}$ ago to reduction in carbonate saturation. Since cooling would also have favored diffusive entry of CO_2 into cells (Raven et al., 2002) it could have slowed CCM development, further reducing cyanobacterial calcification. As Earth emerged from these snowball glaciations, global warming and O_2 rise could have reactivated CCM development, and rising temperature, calcium, and $p\text{CO}_2$ levels would have increased seawater saturation state, stimulating calcification (Riding, 2006). Calcified cyanobacteria became relatively diverse

Calcified Cyanobacteria, Figure 6 Early Cambrian (Botomian) dendrolite-thrombolite reef, $\sim 70\text{ m}$ thick, near Tafraoute, Anti-Atlas Mountains, Morocco. Figures in foreground for scale.

in the earliest Cambrian (Nemakit-Daldynian) (Riding and Voronova, 1984) and were important components of Cambrian reefs (Riding, 2000; Rowland and Shapiro, 2002).

Calcmicrobial reefs and the Cambrian radiation

Calcified microfossils such as *Epiphyton*, *Renalcis*, and *Angusticellularia* are major components of Cambrian reefs (Figures 6 and 7) and similar forms reappeared in the late Devonian. The widespread development of microbial reefs in the early Cambrian may have directly contributed to marine invertebrate diversification. Reefs constructed by calcified microbes appeared in the latest Neoproterozoic, ~550 Ma ago (Grotzinger et al., 2000) and were common in Siberia, Altai Sayan, and Mongolia during the Nemakit-Daldynian (543–526 Ma ago) (Riding, 2002). In the Tommotian, 526–522 Ma ago, this reef-building association was augmented by archaeocyath sponges, with calcified microbes generally being volumetrically dominant (Rowland and Shapiro, 2002), and the reefs became large and cavernous. The exceptional biodiversity that characterizes reefs in general is largely due to the process of reef bioconstruction itself (Cocito, 2004). Rapid accretion of framework with synoptic relief and internal growth cavities creates substrates and spaces that differ in incident light, water movement, and sedimentation, as well as accessibility. This increased habitat size and partitioning generates heterogeneity that promotes biodiversity. For example, Cambrian trilobites show peak diversity in reefal environments (Westrop and Adrain, 2001), and comparison of level-bottom and reef communities in general shows that early Cambrian reefs were centers of diversity (Burzin et al., 2001, Fig. 10.2) with number of reef-building species comparable to that of late

Neogene fossil reefs (Kiessling, 2002, Fig. 20). The expansion of these globally distributed reef communities corresponded with rapid diversification of the shallow marine biota, especially during the Tommotian-early Botomian (~526–517 Ma ago) (Zhuravlev 2001, Fig. 8.1), suggesting a direct link between microbial carbonate development and metazoan evolution.

Phanerozoic record and secular controls

Cyanobacterial sheath calcification: Following their Mesoproterozoic inception, sheath-calcified cyanobacteria remained generally common in shallow-water marine carbonates during much of the Palaeozoic and until the late Jurassic (Arp et al., 2001) (Figure 8b). The abundance of sheath-calcified cyanobacteria during the early Palaeozoic (when CO₂ levels are thought to have been high, see Berner and Kothavala, 2001), suggests that CCMs continued to be induced even when pCO₂ substantially exceeded 10 PAL. This may reflect calcification in habitats subject to carbon limitation that induced CCMs, such as microbial mats and reefs (Riding, 2006). Nonetheless, enhancement of CCMs by overall decline in atmospheric CO₂ could be reflected by increased calcified-sheath abundance in the Mississippian, ~335 Ma ago (Riding, 2006) (Figure 5). However, it seems that this increase in calcified-sheath abundance promoted by falling CO₂ was itself terminated by subsequent steep decline in seawater saturation state ~325 Ma ago, before the end of the Mississippian (Figure 8a).

Broad similarities between calcified-sheath abundance and carbonate saturation are suggested by peaks in the late Cambrian (~500 Ma), late Silurian (~420 Ma), late Devonian (~370 Ma), late Triassic (~220 Ma), and late

Calcified Cyanobacteria, Figure 7 Early Cambrian calcimicrobial reef framework, showing clusters of mainly pendant filaments, early cement and geopetal cavity fill. Near Taroudannt, Anti-Atlas Mountains, Morocco. Width of view ~35 cm.

Calcified Cyanobacteria, Figure 8 Comparison of (a) Marine saturation ratio (Ω) for calcite, calculated from estimates of seawater and atmospheric composition, and (b) abundance of marine sheath-calcified cyanobacteria (Arp et al. 2001, Fig. 3d) (from Riding and Liang, 2005, Fig. 5). Obliquely ruled areas indicate five intervals approximately 500, 420, 370, 220, and 150 millions of years (Myr) ago where peaks of calculated saturation ratio broadly coincide with increased abundances of calcified cyanobacteria. This correspondence supports the view that cyanobacterial calcification has been increased at times of generally elevated seawater saturation for CaCO_3 minerals. The horizontally ruled area indicates the interval ~120–80 Myr ago in which high calculated saturation contrasts with low abundance of calcified cyanobacteria. This anomaly could reflect lowered Cretaceous carbonate saturation due to widespread deposition of pelagic carbonate by coccolithophore algae and globigerine foraminifers, since biological removal of CaCO_3 is not incorporated into the calculation of saturation values.

Jurassic (~150 Ma) (Figure 8), supporting the view that saturation state has significantly influenced the degree of cyanobacterial sheath calcification over geological time (Riding and Liang, 2005).

Reduced abundance of sheath-calcified cyanobacteria ~120–80 Ma ago contrasts with calculated saturation state which is elevated during this interval. This anomaly is thought to reflect reduction in actual (as opposed to calculated) saturation state due to burial of CaCO_3 precipitated as calcified skeletons by plankton such as coccolithophore algae and globigerine foraminifers (Riding and Liang, 2005). Such biological removal of calcium is not included in the input used to calculate the saturation values shown. This effect of planktic calcifiers on the seawater system may have continued into the Palaeogene. During the past 50 Ma, from the early Eocene onward calculated saturation has declined steeply in response to low values of Ca^{2+} ions and pCO_2 , and this is consistent with scarcity of marine calcified cyanobacteria. Consequently, although low pCO_2 values during the Cenozoic (see Berner and Kothavala, 2001) are expected to induce cyanobacterial CCMs, the absence of sheath calcification in marine cyanobacteria presumably reflects the overriding effect of low carbonate saturation.

Biogenic whittings: It can be inferred that, following the development of CCMs in the mid-Proterozoic, picoplanktic cyanobacterial activity could have been an important source of marine carbonate mud whenever inorganic carbon could be a limiting resource, as in plankton blooms (Rost et al., 2003), even when overall atmospheric CO_2 levels were high. If this is correct, then the principal factor determining biogenic whiting occurrence would have been carbonate saturation state. Calculations suggest that saturation was relatively elevated during much of the early-mid Palaeozoic and parts of the Mesozoic (Riding and Liang, 2005; and Figure 8a).

The origins of micrite are notoriously difficult to interpret even in present-day seas, and it is known that calcified green algae can also be significant producers (Stockman and Ginsburg, 1967). How can the possible contribution of biogenic whittings therefore be assessed in the geological past? One line of reasoning is to assume that sheath-calcified cyanobacteria reflect generally similar conditions to those that favor picoplanktic whiting precipitation. The geological record of sheath-calcified fossils such as *Girvanella* is relatively well-documented, and they show marked fluctuations in abundance (Arp et al., 2001, Fig. 3d) (Figure 8b). It could therefore be predicted that picoplanktic mud should show a similar pattern of

abundance, with peaks for example in the late Cambrian, Devonian-Mississippian, and late Jurassic. It should be possible to test whether carbonate mud was relatively abundant at these times. It is also possible that biogenic whittings – and sheath calcification – should have been further intensified whenever $p\text{CO}_2$ levels fell to levels near or below ~ 10 PAL, as for example ~ 350 Ma ago (Figure 5).

Cenozoic decline in seawater carbonate saturation, suggested by calculations based on modeled values (Riding and Liang, 2005, Figs. 5a and 8a), would be expected to have reduced biogenic whiting precipitation. Certainly, sheath calcification is scarce to absent during most of the past 100 Ma (Arp et al., 2001, Fig. 3d) (Figure 8b). In this context, it is not surprising that there is uncertainty whether present-day marine whittings on the Bahaman Banks are biogenic or mainly reflect sediment resuspension (Broecker et al., 2000). From a geobiological perspective, however, even if present-day marine conditions do not greatly favor phytoplankton-stimulated precipitation of whittings, these may have been very important at times in the geologic past environment when carbonate saturation state was sufficiently high. If this is correct, biogenic whittings could account for a substantial part of the carbonate mud that accumulated on shallow shelves between the late Mesoproterozoic and Mesozoic.

Summary

Calcified cyanobacteria are easily overlooked fossils, yet their long history coupled with their sensitivity to environmental controls on their calcification, make them potentially significant indices of changes in seawater chemistry and atmospheric CO_2 level throughout the Proterozoic and Phanerozoic. Locally they are also sedimentologically important reef components, and they have played a major role in the formation of calcimicrobial thrombolites that are especially widespread in the Neoproterozoic and early Palaeozoic. At the present day their vanishing scarcity in marine environments is thought to reflect relatively low seawater carbonate saturation that has persisted throughout the Cenozoic. However, their local abundance in oncoids and tufas of freshwater calcareous streams and lakes, and their involvement in lacustrine whittings, are reminders of the ability of cyanobacteria to promote intense CaCO_3 deposition when conditions that include ambient saturation state, are favorable.

CALCITE PRECIPITATION, MICROBially INDUCED

Tanja Bosak

Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Microbially induced calcite precipitation describes the formation of calcium carbonate minerals from a solution due to the presence of microbial cells, biosynthetic products, or metabolic activity.

Calcium carbonate precipitation

The most basic requirement for the precipitation of calcium carbonate (CaCO_3) minerals, calcite, and aragonite is that the product of the concentrations of calcium $[\text{Ca}^{2+}]$ and carbonate ions $[\text{CO}_3^{2-}]$ exceeds the solubility product of calcite (Equation 1) and aragonite, respectively.

$$[\text{Ca}^{2+}][\text{CO}_3^{2-}] > 10^{-8.35} \quad (1)$$

The solubility of carbonate minerals depends on the temperature and pressure, decreasing with increasing temperatures and increasing with the increasing pressure. When a solution is in equilibrium with carbon dioxide, $[\text{CO}_3^{2-}]$ is determined by pH. In solutions that are undersaturated or not highly saturated, such as modern seawater, the biological activity can strongly control the precipitation of CaCO_3 . Biological processes exert considerably less control on the precipitation of CaCO_3 in environments characterized by high temperature, high pH, and high evaporation and degassing rates such as soda lakes, hot springs, caves, and freshwater tufas.

Microbial processes that promote the precipitation of CaCO_3

Culture-dependent and culture-independent studies have shown that microbes (Bacteria and Archaea) can induce extracellular precipitation of calcium carbonate minerals by:

- Increasing the local pH and the concentration of carbonate ion
- Promoting the nucleation of calcium carbonate minerals and removing the kinetic inhibitors of CaCO_3 precipitation.

Increase in local pH and the concentration of carbonate ion

Because the concentration of carbonate ion increases with the increasing pH, the precipitation of calcium carbonate minerals will also increase with the increasing pH. Many microbial metabolic processes can increase the pH and/or the concentration of carbonate ions: sulfate reduction in marine sediments (Dupraz and Visscher, 2005; Van Lith et al., 2003; Visscher et al., 2000), oxygenic

TERRESTRIAL DEEP BIOSPHERE

Christine Heim
University of Göttingen, Göttingen, Germany

Synonyms

Continental deep biosphere; Subterranean biosphere

Definition

The terrestrial deep biosphere comprises ecosystems in the marine (e.g., shelf-sediments) and continental subsurface, beneath the rhizosphere or bioturbated zone. The habitable depth is limited by space (rock porosity), the availability of water and in particular the maximum viable temperature depending on the local geothermal gradient (Gold, 1992; Pedersen, 1993, 2000, 2001, 2002; Stevens, 2002).

Introduction

Microbial life exists in, and seems to be adapted to all kinds of ecological niches on earth. From the early 1930s, increasing numbers of publications report on the occurrence of microorganisms in deep terrestrial settings, such as coal mines (Lipman, 1931, 1937; Lieske, 1932) and deep formation waters from oil drilling, as deep as 2,000 m (Ginsburg-Karagitscheva, 1933; Issatchenko, 1940). During the following decades the scientific interest in subsurface microbiology focused on the effects of microorganisms on oil and gas exploration, such as corrosion of drilling devices, oil transformation, but also the role of microorganisms in the biological origin of natural gas resources (Bailey et al., 1973; Belyaev et al., 1983; Colwell et al., 2004; Lollar et al., 2006; Zobell, 1945). Deep subsurface microorganisms have a potential impact not only on oil and gas exploration, but also on

groundwater (Chapelle, 2000), long-term storage of nuclear waste (Boivin-Jahns et al., 1996; Christofi and Philip, 1997; Hersman, 1997; Pedersen, 1993, 1997; Pedersen et al., 2008), and finally, implications for the origin of life and the search for extraterrestrial life (Cockell, 2004; Faison, 2003; Stevens, 1997a).

Scientific continental drilling (ICDP), and also site investigations for the storage of nuclear waste for a better understanding of geological, hydrological, and biogeochemical processes in the deep continental crust, supported the development of contamination minimizing, drilling, sampling, and analytical techniques (Abyzov et al., 2001; Griffin et al., 1997; Pedersen, 1993 (and references therein); Pedersen et al., 2008; Russel, 1997). Using enhanced drilling and sampling techniques, a broad diversity of microorganisms living under extreme conditions (extremophiles), i.e., under elevated temperatures and high pressure conditions, was observed (Gold, 1992; Boone et al., 1995; Bonch-Osmolovskaya et al., 2003; Kotelnikova et al., 1998; Lin et al., 2006; Szewzyk et al., 1994; Sahl et al., 2008). Whether the organisms observed in the deep terrestrial subsurface are indigenous or derive from surface contamination has been a major issue since the first decades of exploration and is still (even though more advanced sampling techniques are now available), an important question to be considered (Farrell and Turner, 1932; Griffin et al., 1997; Haldemann, 1997; Lieske, 1932; Lipman, 1937; Pedersen, 1993; Phelps et al., 1989; Russel, 1997; Stevens, 2002). Furthermore comprehensive sampling (contamination controlled sampling) and careful data interpretation is matter of major importance (Hallbeck and Pedersen 2008; Lehman et al., 1995; Zhang et al., 2006).

The deep terrestrial biosphere

Numerous reports about diverse, well adapted, active microorganisms, being most likely indigenous, and

occurring down to a depth of several km, rise the questions of (a) how the organisms got down there, (b) how are they able to maintain, i.e., life and growth, (c) what are the limiting factors for life in the deep biosphere.

There are different theories about microbial migration or transport into the deep subsurface can happen. One possibility is the transport of microorganism within groundwater aquifers as underground rivers (Karst systems) or percolating through the sediment or fracture systems. Groundwater may reach depths of several hundreds of meters and may have intervals from hundreds to thousands of years (Moser et al., 1988; Seiler and Lindner, 1995; Simpkins and Bradbury, 1992). Further, it is assumed that living microbial matter is buried with the sediments, thus migrating vertically as a part of the rock cycle. As a consequence, some microorganisms must be capable to survive for millions of years. Reports on the detection and isolation of bacteria from the Taylorsville Triassic Basin from 2.7 km depth (Boone et al., 1995), and from the Piceance Basin of western Colorado from 858 m depth (Colwell et al., 1997) support this scenario.

General requirements for life are the availability of water, space, nutrients (O, C, H, N, Ca, P, and S), and trace elements (Fe, Ni, Mn, W, Mo, V, Zn, Cu, Co, Se, and Cr). Being independent from photosynthesis, subterranean organisms have to adapt their metabolism to local resources or form dormant stages, in order to survive at great depth (Amy, 1997; Dobretsov et al., 2006; Kieft and Phelps, 1997; Pedersen, 1993; Stevens, 2002). Since the discovery of the first subsurface microorganisms, and the subsequent identification of a broad variety of aerobic, anaerobic, autotrophic, and heterotrophic microbes, the potential carbon and energy sources available, and depth, were intensively debated and approved. One major theory is the deep hydrogen-driven biosphere hypothesis (Pedersen, 1997), where acetogenic bacteria, acetoclastic methanogens, and autotrophic methanogens consume abiotic, deep crustal H_2 as an energy source and CO_2 as carbon source. These organisms could be considered as the primary producers in the deep terrestrial biosphere. Experimental studies, calculating the production rates of radiolytic H_2 , support the potential microbial consumption of H_2 (Lin et al., 2005). Beside H_2 as electron donor, chemotrophic organisms can use, for example, methane (CH_4), elemental sulfur (S^0), sulfite (SO_3^{2-}), thiosulfate ($S_2O_3^{2-}$) with water H_2O , nitrate (NO_3^-), sulfate (SO_4^{2-}) or iron (Fe (III)), thereby forming nitrogen gas, hydrogen sulfide (H_2S) and ferrous iron, respectively (Amend and Teske, 2005 and references therein; Kieft and Phelps, 1997; Stevens, 2002).

Numerous microorganisms observed in the deep subsurface are not only metabolically well adapted, they also manage to survive and reproduce under extreme conditions, such as hot or freezing temperatures, high pressure, alkaline or acidic conditions, and high salinity. Examples of these extremophiles and references are listed below in the section of the respective deep terrestrial environment. Moreover, some microorganisms are able to get into

a dormancy stage by forming spores, cysts, or other types of resting cells and survive starvation, desiccation periods, exposure to extreme temperatures, and elevated background radiation (Amy, 1997; Burke and Wiley, 1937; Johnson et al., 2007; Ponder et al., 2005; Suzina et al., 2004).

Regarding these adaptation mechanisms and considering the ongoing discovery of unknown microorganisms, new metabolic pathways and adaptation mechanisms, it is difficult to define the limits of life in the terrestrial deep biosphere. These actual limits may be due to a combination of several factors: with increasing depth, the growing load of the overlying rocks or ice masses progressively decreases the pore space available, temperature rises due to the geothermal gradients and the water activity changes with increasing temperatures and pressures (Gold, 1992; Pedersen, 1993, 2000; Stevens, 2002).

Terrestrial deep biosphere environments

Pedersen (2000) divided the terrestrial deep biosphere into continental sedimentary rocks, ancient salt deposits, aquifers in igneous rocks, and caves, whereas Stevens (2002) subdivided the deep biosphere of the continental crust into sedimentary environments, permafrost, ice sheets and glaciers, and bedrock environments. Salt deposits and permafrost soils are sediments by definition, and therefore, in this chapter, they are discussed in the section sedimentary environments. Caves exhibit a great variety of different ecosystems that might serve as models for the formation of special adaptations or symbioses and may therefore represent a link between surface and subsurface environments (Dattagupta et al., 2009; Pedersen, 2000).

Sedimentary environments

Since the beginning of the last century, microorganisms in deep sedimentary environments have been frequently found and described from exploration sites, for example in coal (Burke and Wiley, 1937; Lieske, 1932; Lipman, 1931, 1937). Later when advanced drilling techniques and modern sequencing methods became available, a more precise characterization of these microorganisms is possible. A strict anaerobe, *Bacillus* species (*Bacillus infernus*) was isolated from drill core samples obtained from 2,700 m depth, from the Triassic Taylorsville basin (Boone et al., 1995). Several sediment core samples from 856 to 2,096 m from the Piceance Basin of Colorado contained Fe(III)-reducing and -fermenting bacteria (Colwell et al., 1997). Krumholz (2000) reported microbial communities within Cretaceous rocks in New Mexico, where living sulfate-reducing bacteria (SRB) and acetogens were found at the interface of porous sandstone and dense organic-rich shale. Later studies of the same site revealed high numbers of Fe(III) and S-reducing bacteria (Kovacik et al., 2006). Sass and Cypionka (2004) isolated moderately thermophilic SRB in porous sandstones from 600 to 1,060 m depth. In coal seam groundwater within 843 to 907 m depth microbial communities of

methanogenic archaea, denitrifying, acetogenic, and SRB where detected (Shimizu et al., 2007). Thermophilic archaea and bacteria, including SRB, are common in oil reservoirs and geothermal fluids (Bonch-Osmolovskaya et al., 2003; Kimura et al., 2007; Zavarzina et al., 2007; Zobell, 1945). Culturing experiments and biomarker studies of 170 million years old claystone indicate the presence of active SRB within the rock (Mauclaire et al., 2007).

A special form of sedimentary environment is salt deposits: massive salt deposits have formed mainly due to marine transgression and regression cycles within epicontinental seas. Halophilic bacteria were described by Vreeland et al. (1998) from salt deposits in New Mexico and Gruber et al. (2004) isolated halophilic archaea in alpine salt deposits. Whether the halophilic microorganisms are indigenous and survived for millions of years in the salt, is still unclear (McGenity et al., 2000). However, the isolation of viable *Halobacterium salinarum* from brine inclusion within 9,600-years-old halite crystals (Mormile et al., 2003) indicates long-term survival of the microorganisms enclosed in salt deposits.

Permafrost soils are composed of silt, loam, peat, organic material from plants, top soil, and ice. Although temperatures in permafrost regions range between -10 and -30°C viable microorganisms have been detected in frozen sediment samples from Siberia, Alaska, Canada, and Antarctica (Vorobyova et al., 1997). Methanogenic archaea are presumably responsible for the production of high amounts of methane in permafrost soils (Rivkina et al., 2000, 2004). Gilichinsky et al. (1992) observed not only prokaryotes in Pliocene and Pleistocene sediments, even eukaryotic organisms were found in Holocene sediments.

Bedrock environments

Igneous and metamorphic rocks contain considerably less organic matter and pore space compared to sediments. Sampling of microorganisms is a problematic issue, as drilled rock material is often contaminated by drilling fluids (Pedersen, 2000; Hallbeck and Pedersen, 2008). However, investigations of a deep biosphere in igneous rocks were performed using the fracture and well water, drilling fluids, and groundwater aquifers. In deep granitic aquifers of the Fennoscandian shield, anaerobic thermophilic fermenting bacteria and SRB (Szewzyk et al., 1994), methanogens, homoacetogens (Kotelnikova and Pedersen, 1998; Pedersen, 2000; Kotelnikova, 2002), yeasts (Ekendahl et al., 2003), viruses (Kyle et al., 2008), and bacteriophages (Eydal et al., 2009) were observed. The detection of fungi in deep biosphere environments was also reported by Reitner et al. (2005), describing hyphae from unknown fungal mycelia in the Triberg Granite (Germany). In deep granitic fracture water and rock cores from the Henderson mine (Colorado), iron-oxidizing bacteria and the "Henderson candidate division" were detected (Sahl et al., 2008). In deep anaerobic and alkaline aquifers within the Columbia River Basalt Group,

SRB and metal-reducing bacteria were described by Fry et al. (1997). Drilling fluids from boreholes at 2,290–3,350 m depth, from the Chinese Continental Drilling Program, exhibited a huge diversity of extreme thermophilic, anaerobic chemoorganotrophs, anaerobic Fe(III) reducers, halotolerant, alkaliphilic microorganisms (Zhang et al., 2006). Lin et al. (2006) report about thermophilic SRB in deep alkaline saline groundwaters in Archaean metabasalt. A remarkable finding was a star shaped bacterial morphotype at 1,700 m depth in a South African platinum mine, observed by Wanger et al. (2008).

Ice sheets and glaciers

Microbiological investigations of ice cores obtained above the subglacial lake Vostok, Antarctica, exhibited various microorganisms from moraine material, from shallow regions of the glacier, but also presumably from the lake water (Abyzov et al., 2001). Poglazova et al. (2001) described Cyanobacteria and microalgae occurring in accreted ice of the subglacial lake Vostok. Highly diverse microbial communities in 120,000-years-old deep glacier ice cores from Greenland were described and isolated by Miteva and Brenchley (2005), Miteva et al. (2004).

General remarks

Fossil deep biosphere, evolutionary aspects, and implications for extraterrestrial life

As research on the deep biosphere continues, novel organisms, metabolic pathways, and adaption mechanisms will certainly be discovered. A look at the different subsurface environments shows that a generalization of the microbial diversity and adaption mechanisms is rather impossible as they all host their own specialized ecosystems.

Learning more about life in deep subterranean environments, may help to understand how life might have evolved and survived during meteoric impacts, increased rates of volcanic activity, or a potential global glaciation (Snowball Earth). In fact, geothermal waters, H_2 and CH_4 degassing volcanic or plutonic rocks may have served as local nutrient and energy sources for chemotrophic ecosystems (Dobretsov et al., 2006). Models about the habitability of the Hadean earth indicate that even the late heavy meteoric bombardment, around 3.9 Ga would not have been able to sterilize the primeval biosphere of the earth crust, considering the existence of a near and subsurface biosphere (Abramov and Mojzsis, 2009). Traces of a fossil subterranean biosphere were observed in metasedimentary rocks from Timmins (Canada) from the late Archaean (Ventura et al., 2007) and Bons et al. (2009) report about fossilized microbes within 585 Ma old calcite veins from Oppaminda Creek (Australia).

Increased interest for research in deep terrestrial, means also extreme environments, is its implication for extraterrestrial life. A better understanding of the earth's deep biosphere allows the development of models to understand

general biogeochemical processes not only for our earth but maybe for biogeochemical processes on other planets. For example, permafrost soils on Mars may comprise recent or ancient life (Gilichinsky et al., 1992; Rivkina et al., 2000, 2004) or Jupiter's satellites may have ice-covered lakes similar to lake Vostok (Abyzov et al., 2001) serving as a potential deep biosphere environments.

THIOESTER WORLD

Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

Christian de Duve (1991, 1994, 1995) proposed a Hadean “Thioester World” which should have preceded the succeeding RNA world. Thioester molecules were probably very common in the proposed “primordial organic soup”. Thioesters are formed when a ‘thiol’ joins a carboxylic acid (R'–COOH) under acidic and high temperature environmental conditions. The general form is written as an organic group (R) bonded with sulfur and hydrogen, hence R-SH. H₂O is released in this process, and forms finally a thioester: R–S–CO–R'. The “Thioester World” represents a hypothetical very early stage in the origin of life that could have provided the energetic and catalytic framework of a protometabolic set of primitive chemical reactions, like in the transaction of molecular groups, and in Redox-reactions. Thioesters were probably involved in the formation of energy-rich phosphates via acylphosphates and pyrophosphates as precursor compounds. The thioester bond is a high-energy bond and probably thioesters had the same function as ATP as an energy supplier. With the help of thioesters amino acids (AS) could also spontaneously polymerise and form first simple proteins. The “primordial organic soup” was enriched with AS may be provided by carbonaceous chondrites and comets which collided with the early earth and the early earth was also characterized by an intense volcanic activity. This volcanic activity generated H₂S and thiols are expected to arise readily in these H₂S-rich fluids. In laboratory experiments, imitating the Hadean conditions on Earth, it was possible to obtain cysteamine, b-alanine and pantonic acid known as ‘pantetheine’ which is a precursor of coenzyme A (Keefe et al., 1995). The thioester world is an important hypothesis in the understanding of early life processes which may explain essential reactions expected in the prebiotic world.

DEEP BIOSPHERE OF THE OCEANIC DEEP SEA

Kristina Rathsack, Nadia-Valérie Quéric, Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition and overview

Although used in many different ways, the term “biosphere” is principally defined either as zone in which life occurs, thereby overlapping the atmosphere, the hydrosphere, and the lithosphere, or as the entity of living organisms on Planet Earth. Both perceptions commonly focus on the Earth's near-surface environment, with all domains sharing solar energy used in the process of photosynthesis. The deep-sea realm takes a special position in this context, as deep-sea pelagic and the majority of benthic organisms live in the ocean's aphotic zone and inhabit the widespread abyssal plains, respectively. For a long time, their main food source has been considered to be based on particulate organic matter (POM) from the ocean's surface primary production and its sedimentation to abyssal depths (Gage and Tyler, 1991 and references therein, D'Hondt et al., 2002, 2004). With the discovery of “ocean vents” in the late 1970s (Corliss et al., 1979), this general perspective was broadened by the perception of the enormous potential of chemical energy through the reaction of seawater, rock material, and fluids rising from the Earth's interior. According to this concept of energy for life, the term ‘surface biosphere’ has been opposed to ‘sub-surface biosphere’ (also commonly found in literature as ‘deep biosphere’). Following this definition, the deep-seafloor with its highly diverse topography from heterotrophic to pure chemotrophic habitats has to be treated as a transition zone between both biospheres. Opposed to the “*deep hot biosphere*” (Gold, 1992), occurring by definition in oceanic as well as terrestrial subsurface environments, stands the “*deep cold biosphere*” as defined for permafrost sediments (Vorobyova et al., 1997) and ice cores from the depths of Lake Vostoc (Venter, 2001).

Life in the deep sea

Comprising approximately 65% of the Earth's surface, the deep-sea environment is characterized by hyperbaric, aphotic, and low-temperature conditions and highly

diverse seascapes. Canyons, seamounts, ridges, fractures, and trenches, but also biogeochemical oases such as cold seeps, mud volcanoes, carbonate mounds, brine pools, gas hydrates, hot vent systems, and deep-water coral reefs provide ample niches for a highly diverse pelagic and benthic deep-sea community (Tyler, 2003). It was only during the construction of the transoceanic telegraphic communication network that people realized the ocean's topographic alterations and astonishing depths. In 1861, the repair of an overgrown cable from 1,800 m water depth in the Mediterranean finally aroused the scientific community which by then adhered to Edward Forbes' theory on a completely ‘azotic’ zone below a water depth of 550 m. Though, 11 years had elapsed before the first global, scientific expedition onboard the “*Challenger*” (1872–1876) finally convinced people that a flourishing life in fact exists in the deep-sea realm. Numerous, further expeditions and a rushing development of technical facilities allowed deep-sea researches in 1960 to reach even the ocean's deepest surveyed point, the Challenger Deep at 10,911 meters below sea level (mbsl), located at the southern end of the Mariana Trench within the western Pacific Ocean (Piccard and Dietz, 1961). Since then, several studies on large-scale patterns and the zoogeographical origins of deep-sea organisms evidenced a high macrobenthic diversity (Gage and Tyler, 1991 and references therein). These organisms display a depth-dependent zonation as a result of basin age, deep currents (as barriers or dispersal), topographic boundaries, disturbance processes, and sedimentation in connection with depth-related environmental patterns (for review see Levin et al., 2001; Stuart et al., 2003). Macro- and meiofauna are losing importance with increasing water and sediment depth, whereas microorganisms like bacteria, archaea, and fungi account for up to 90% of the deep-sea benthic biomass (Pfannkuche, 1992). Sinking particles may carry large numbers of microorganisms from upper zones (10^8 – 10^{10} cells $m^{-2} d^{-1}$), inoculating deep marine surface sediments with an autotrophic and heterotrophic microbial community, as demonstrated by results from sediment traps (Turley and Mackie, 1995; Danovaro et al., 2000; Vanucci et al., 2001) or the deep-seafloor (Lochte and Turley, 1988).

Particulate organic matter (POM)

Due to the fact that most deep-sea benthic species are deposit feeders (Sanders and Hessler, 1969), the locally qualitatively and quantitatively, variable import of POM from the ocean's surface waters plays a crucial role for macro-, meio-, and microorganisms living in deep surface sediments (Goody and Turley, 1990). Mainly consisting of phytoplankton, marine snow, fecal pellets, (dead) zooplankton and molts, this material undergoes different steps of degradation during its passage from the photic, epipelagic (0–200 mbsl), through the mesopelagic (200–1,000 mbsl) to the actual deep-sea zones, in particular the bathypelagic (1,000–4,000 mbsl), the abyssal

(4,000–6,000 mbsl), and the hadal zone (6,000–11,000 mbsl). Depending on the residence time in the water column, the bioavailable part of POM finally reaching the deep-seafloor may be small (De La Rocha and Passow, 2007 and references therein). The refractory remainders such as animal skeletons are continuously accumulating at the seafloor and turn into deeply buried sediment over time, thereby representing the largest global reservoir organic carbon (Parkes et al., 2000 and references therein).

Deep-sea sediment types

Grain size (Gray, 1974) and sediment heterogeneity (Etter and Grassle, 1992) may additionally govern community composition and distribution of macro-, meio-, and micro-organisms in deep-sea benthic environments. In relation to their basic sources, deep-sea sediments may be biogenic (POM from pelagic primary production, benthic in-situ production), lithogenous (terrestrial weathering and transport by wind and rivers), hydrogenous (precipitation from seawater or pore water), volcanic, or cosmic (Seibold and Berger, 1996). According to grain size and settling velocity, lithogenous gravel and sandy fractions usually are deposited along the coast, while silt and clay are transported farther offshore through waves and currents, hence dominating the basically biogenous deep-sea sediments. Regional deviations may be linked to currents, downslope slides, submarine canyon dynamics, or to a release of ice-trapped rock material in polar waters (e.g., Ramseier et al., 2001). Covering almost one-half of the shelves and more than half of the deep ocean bottom, biogenous sediments mainly consist of calcite, aragonite, opal, and calcium phosphate, originating from foraminifera, diatoms, and radiolarians (Hay et al., 1988).

Deep biosphere of deep-sea sediments

Microbiological studies on sediment cores collected during several cruises of the Deep Sea Drilling Project (DSDP), the Ocean Drilling Program (ODP), and the Integrated Ocean Drilling Program (IODP) gave evidence for the presence of complex microbial communities in deeply buried marine sediments down to several hundred meters below seafloor (e.g., Whelan et al., 1986; Parkes et al., 1994; Roussel et al., 2008). Most striking, new insights into subsurface microbiology were gained during the ODP cruise Leg 201 to the equatorial Pacific Ocean and the continental margin of Peru, including sites recognized as most typical for oceanic subsurface environments (D'Hondt et al., 2002). A large fraction of the sub-seafloor bacteria has been proven to be alive and culturable, displaying turnover rates (based on sulfate reduction as dominating mineral process at these sites) comparable to surface sediment communities (D'Hondt et al., 2004; Schippers et al., 2005).

After a logarithmic decline within the uppermost 6 meters below seafloor (mbsf) (Parkes et al., 1994) to about 40 mbsf (Schippers et al., 2005), bacterial cells have proven to be more or less evenly distributed down to

several hundred mbsf. Local peaks within these deeply buried sediments seem to mirror sulfate (diffusing from crustal fluids) and methane (from in-situ production) concentration shifts (Engelen et al., 2008). However, published variations of absolute cell numbers (by a factor of up to 3) have to be treated with caution: varying estimations not only depend on the geochemical conditions at the respective sampling sites, but also on the enumeration techniques applied. Calculations based on early results revealed that sub-seafloor sediments comprise – at least – half of all prokaryotic cells and up to one-third of the living biomass on Earth pointing to a slow-growing strategy of high biomass in areas of low-energy flux (Whitman et al., 1998).

The prokaryotic community in deeply buried sediments can not exclusively be traced back to contaminations from biologically active surface layers or reactivation of spores and dormant cells (Parkes et al., 2000 and references therein).

Porewater chemistry data obtained from sites throughout the world's oceans (ODP, DSDP) showed that sulfate reduction, methanogenesis, and fermentation are the principal degradative metabolic processes in subsurface sediments. These results give evidence for significant lower metabolic rates for the subsurface compared to the surface biosphere and for methanogenesis becoming more important the more sulfate gets depleted with increasing sediment depth (D'Hondt et al., 2002 and references therein).

Windows to the subsurface biosphere

Hydrothermal vents

The discovery of the “ocean vents” near Galapagos Island (Corliss et al., 1979) was the first proof for the active movement of the gigantic oceanic plates of the Earth's crust creating series of cracks in the ocean floor, teeming with life. At these discharge areas, hydrothermal fluids with temperatures of more than 400°C (Haase et al., 2007) mix up with the cold ocean seawater, resulting in a precipitation of dissolved metals and in the formation of characteristic chimneys over time. Iron and sulfide precipitates turn the smokers black (“black smokers,” Figure 1), while barium, calcium, and silicon minerals result in “white smokers.” Thermal precipitation and/or direct magma degassing of H₂, H₂S, CH₄, CO, and CO₂ in combination with oxygen as electron acceptor provide enough energy to support a highly productive and physiologically diverse chemoautotrophic microbial community (Reysenbach and Shock, 2002).

As the highly diverse and dense hot vent macrofauna (e.g., vestimentiferan tubeworms, bivalve mollusks, provannid gastropods, alvinellid polychaete, and bresiliid shrimps) cannot feed on the released chemicals themselves, they either feed on chemoautotrophic microbes or host them as symbionts. The predominant endosymbionts are mesophilic to moderately thermophilic chemoautotrophs (mostly Gammaproteobacteria), whereas most

episymbionts belong to the Epsilonproteobacteria, which can oxidize H_2 and sulfur compounds while reducing oxygen, nitrate, and sulfur compounds (for review, see Nakagawa and Takai, 2008). The vent habitat proved to harbor methanogens (*Methanococcus*), sulfate-reducers (*Archaeoglobus*), and facultative autotrophs and heterotrophs such as the thermophilic aerobic *Thermus* and *Bacillus* (Harmsen et al., 1997) or, for example, *Thermococcus*, *Pyrococcus*, *Desulfurococcus* (Prieur et al., 1995; Teske et al., 2000; Nercessian et al., 2003; Schrenk et al., 2003). Generally detected archaeal phylotypes were affiliated with hyperthermophilic *Crenarchaeota*, *Euryarchaeota* Group I, II, III (Takai and Horikoshi, 1999) and the “Deep-sea Hydrothermal Vent Euryarchaeotal Group” (Hoek et al., 2003).

Cold seeps and mud volcanoes

Just a few years after the discovery of the hydrothermal vent systems, cold seep ecosystems were reported from active and passive continental margins and subduction zones all over the world (Aharon, 1994 and references therein).

High-pressure, low oxygen and low-temperature conditions favour the formation of marine gas hydrates. In the subsurface realm, such gas reservoirs are stored in a crystalline form, whereas they get dissolved in pore waters and finally leave the sediment surface in gaseous form. High fluxes of methane, sulfide, and other reduced elements characterize these ecosystems such as cold seeps, hydrocarbon vents and mud volcanoes, often leaving mineral precipitation in their immediate surroundings. Coupled to sulfate reduction, rich bacterial and archaeal communities perform anaerobic oxidation of hydrocarbons, but predominately of methane (Boetius et al., 2000; Borowski et al., 2000; Treude et al., 2005).

Deep Biosphere of the Oceanic Deep Sea, Figure 1 Black smoker “Candelabra,” Logachev hydrothermal field, Mid-Atlantic Ridge (3,000 m water depth). (By courtesy of MARUM, Center for Marine Environmental Sciences, Bremen, Germany.)

Conversion of methane is mainly mediated by two different groups of anaerobic methanotrophic archaea (ANME-I and ANME-II) (Nauhaus et al., 2005), forming syntrophic consortia with the sulfate-reducing bacteria (SRB) *Desulfosarcina* and *Desulfococcus* (Hinrichs et al., 1999; Boetius et al., 2000; Michaelis et al., 2002; Knittel et al., 2003).

The methane-emitting Haakon Mosby Mud Volcano (HMMV, Barents Sea) has shown to harbor three key communities in methane conversion such as aerobic, methanotrophic bacteria (Methylococcales), anaerobic methanotrophic archaea (ANME-2) thriving below siboglinid tubeworms, and a previously undescribed clade of archaea (ANME-3) associated with bacterial mats (Niemann et al., 2006). Similarly, some cold seeps on the deeper Black Sea shelf are characterized by intense methane bubble discharge, mainly related to microbial methanogenesis (Pape et al., 2008 and references therein). Diffuse gas seeps in more shallow, oxic Black Sea waters often exhibit a netlike coverage of microbial mats similar to *Beggiatoa*-mats observed at HMMV (Figure 2). *Beggiatoa* spp. are discussed as keystone members of seep communities owing to their ability to (directly and indirectly) influence the metabolic activity of δ -Proteobacteria, Planctomycetales, and ANME archaea by providing sulfate and ammonia as reactants (Mills et al., 2004).

The question remains, to which extent such seep systems influence the global methane cycle, as the quantification of bubble dissolution and/or the release of methane-rich pore fluids from the sediment into the hydrosphere is difficult to achieve (Vogt et al., 1999; Reeburgh, 2007). Niemann et al. (2006) estimated that methanotrophy at active marine mud volcanoes consumes less than 40% of the total methane flux, due to limitations

Deep Biosphere of the Oceanic Deep Sea, Figure 2 Shallow-water cold seep area, Ukrainian shelf, Black Sea. White, net-like microbial mats are constructed of sulfide oxidizing bacteria (“*Beggiatoa*”). of the relevant electron acceptors in the upward flowing, sulphate- and oxygen-free fluids.

Deep biosphere of the oceanic crust

The fact that microorganisms are present in the subsurface realm had been reported decades ago in terrestrial subsurface environments (Farrell and Turner, 1931; Lipman, 1931). Early drilling operations performed for commercial purposes such as mining, oil and hot water recovery, and the search for underground waste repositories reported on the existence of a large community of microorganisms obviously involved in geochemical processes in the deep biosphere (Gold, 1992; Pedersen, 1993 and references therein). Hence, it was only in the early 1990s that scientists started to focus on the investigation of prospering life beneath the Earth's crust, thanks to a chance encounter of a deep oceanic, volcanic eruption during a dive onboard the submersible *Alvin*, releasing white microbial bulk mats (Haymon et al., 1993). The upper layers of the oceanic crust are characterized by high basaltic porosity, hosting a vast hydrothermal reservoir (Johnson and Pruis, 2003) inhabited by a microbial community composed of species that are also found in deep-sea waters, sediments, and the deep oceanic crust (Thorseth et al., 2001; Huber et al., 2006). Among the most prominent anaerobic thermophiles indigenous for the oceanic crust, the *Ammonifex* group of bacteria (Nakagawa et al., 2006) or groups within *Crenarchaeota*, *Euryarchaeota*, and *Korarchaeota* (Ehrhardt et al., 2007). Since 3.5 billion years, basalt-associated glass textures and vesicular cavities within the basaltic matrix provide niches for microbial colonization (Furnes et al., 2004; Peckmann et al., 2008). For instance, the fossil record of the oceanic crust even gives evidence for a previous fungal life in deep ocean basaltic rocks (Schumann et al., 2004).

Much effort has been put into the investigation of the deep biosphere of the deep sea during the past 20 years. However, we still are neither aware of the final composition of the living subsurface community, nor of its interrelationship to, for example, crustal fluid-derived compounds, nor of its global impact.

DEEP FLUIDS

See entries “[Terrestrial Deep Biosphere](#),” “[Deep Biosphere of Salt Deposits](#),” and “[Deep Biosphere of the Oceanic Deep Sea](#).”

DEGRADATION (OF ORGANIC MATTER)

Transformations of organic matter within the range of temperatures, pressures and environmental conditions found at or near earth surface environments. If biological activity is confirmed to cause the transformations, termed **biodegradation**. See entries “[Carbon \(Organic, Cycling\)](#)” and “[Carbon \(Organic, Degradation\)](#),” and “[Microbial degradation](#) (of organic matter)” for further reading.

DENITRIFICATION

Denitrification is the biological reduction of nitrate (NO_3^-) to N_2 and, to a minor extent, other gaseous species such as N_2O . See entry “[Nitrogen](#)” for further reading.

DESERT VARNISH

Randall S. Perry
 Imperial College, London, UK

Synonyms

Rock Varnish, *Rock Glaze*, *Silica Glaze*, and *Schutzrinde* were introduced in 1891, from a translation of the French term *manteau protecteur*: “*Schutzrinde*” for all dark coatings, including “*Wustenlack*” a thin, polished coating that may be an eolian polished patina; “*Dunkle Rinden*” as a dark brown to black coating, possibly more similar to Sonoran and Mojave desert varnish; and “*Schweinfurth*,” which describes black coatings on rocks in Egypt that have spread on surrounding sands.

Definition

Desert Varnish. In arid environments such as Death Valley (California), rocks are covered with black opalescent desert varnish ([Figure 1](#)). Desert varnishes have been found in all continents, in locations such as the Gobi, Sonoran, Mojave, Namibian, Victorian, and Atacama

DEEP BIOSPHERE OF SALT DEPOSITS

Helga Stan-Lotter¹, Sergiu Fendrihan²

²Bioresource Center and Advanced Research Association, Bucharest, Romania

Definition

The *biosphere* is defined either as “the place on Earth’s surface where life dwells” (Eduard Suess’ original definition, 1875, in *The Origin of the Alps*), meaning the zone on Earth where life naturally occurs, or in a more narrow sense as just the organisms themselves. Recent advances in microbiology have demonstrated that microorganisms live deep beneath the Earth’s terrestrial surface and that the total mass of microbial life may, in biomass, exceed all animal and plant life on the surface (Whitman et al., 1998). Microorganisms live at such extremes that the “thickness” of the biosphere extends from 5,400 m above sea level to at least 9,000 m below sea level.

Salt deposits are accumulations of solid materials and are usually derived from evaporation of seawater. There are >70 elements dissolved in extant seawater, but only 6 ions make up >99% of all the dissolved salts (wt% in brackets): Na⁺ (30.51), Cl[−] (55.08), SO₄^{2−} (7.69), Mg²⁺ (3.67), Ca²⁺ (1.17), K⁺ (1.10) (Hay et al., 2006).

Introduction

About 250 million years ago the continents on Earth were close together and formed Pangaea, a supercontinent, which persisted for about 100 million years and then fragmented. The land masses at that time were located predominantly in the southern hemisphere. The climate was arid and dry, and the average temperature is thought to have been several degrees higher than at present. This was one of the time periods in the history of the Earth, when

huge salt sediments formed. A total of about 1.3 million cubic kilometers of salt were estimated to have been deposited during the late Permian and early Triassic period alone (250–192 million years ago; Zharkov, 1981); newer research has discovered additional vast salt deposits, which were previously unknown – especially deposits below the Gulf of Mexico, and extensive Miocene salt (about 20 million years old) underlying the Mediterranean Sea, the Red Sea, and the Persian Gulf (Hay et al., 2006).

The thickness of the ancient salt sediments can reach 1,000–2,000 m. When Pangaea broke up, land masses were drifting in latitudinal and northern direction. Mountain ranges such as the Alps, the Carpathians, and the Himalayas were pushed up by the forces of plate tectonics. In the Alpine basin and in the region of the Zechstein Sea, which covered northern Europe, no more salt sedimentation took place after the Triassic period. Dating of the salt deposits by sulfur-isotope analysis (ratio of ³²S/³⁴S as measured by mass spectrometry), in connection with information from stratigraphy, indicated a Permo–Triassic age for the Alpine and Zechstein deposits (Holser and Kaplan, 1966). This age was independently confirmed by the identification of pollen grains in the sediments (Klaus, 1974). Figure 1 shows pollen grains from extinct coniferous trees, which were found in Alpine Permian salt and also in Zechstein salt (Klaus, 1963).

Microorganisms and signature sequences from salt deposits

As recently as 1981, Larsen (1981) described mined rock salts as free from bacteria, although isolations of halophilic microorganisms from ancient salt sediments had occasionally been reported since the early decades of the twentieth century (see Grant et al., 1998; McGenity et al., 2000). From Alpine Permian rock salt, which was collected from the salt mine in Bad Ischl, Austria, a haloarchaeon (see “*Halobacteria – Halophiles*”) was

56

Deep Biosphere of Salt Deposits, Figure 1 Photomicrograph of winged pollen grains of the genus *Lueckisporites*, found in Alpine Permian salt deposits and in Zechstein salt. *Upper panel: L. virkkiae*, dimensions $60 \times 40 \mu\text{m}$; *lower panel: L. microgranulatus*, dimensions $64 \times 35 \mu\text{m}$ (From Klaus, 1963 with permission.)

isolated, which was recognized as a novel species and named *Halococcus salifodinae* strain BIp (Denner et al., 1994). This was the first isolate from ancient rock salt, which was formally classified and deposited in international culture collections. Two independently isolated strains, Br3 (from solution-mined brine in Cheshire, England) and BG2/2 (from a bore core from the mine of Berchtesgaden, Germany) resembled *Hc. salifodinae* strain BIp in numerous properties, including the characteristic morphology of coccoid cells arranged in large clusters (see Figure 2, right panel, in “*Halobacteria – Halophiles*”); in addition, rock salt samples were obtained 8 years later from the same site and several halococci were recovered from these samples, which proved to be identical to strain BIp (Stan-Lotter et al., 1999). The data suggested that viable halophilic archaea, which belong to the same species, occur in geographically separated evaporites of similar geological age. Another halococcal isolate from the Bad Ischl salt formation, which differed from the previously described strains, was identified as a novel species and named *Halococcus dombrowskii* (Stan-Lotter et al., 2002). *Hc. salifodinae* and *Hc. dombrowskii* have so far not been found in any hypersaline surface waters, or any location other than salt mines. Recently, a non-coccoid novel haloarchaeon, *Halobacterium noricense* was obtained from a freshly

Deep Biosphere of Salt Deposits, Figure 2 Drilled bore cores, stored in a wooden box, from the Alpine salt mine in Altaussee, Austria obtained from about 500 m below surface. Pink portions represent halite (NaCl), containing traces of hematite; grayish portions contain mostly anhydrite (CaSO_4).

drilled bore core (Figure 2) at the salt mine in Altaussee, Austria (Gruber et al., 2004). Other isolates from ancient salt deposits include a single rod-shaped *Halobacterium* from 97 000 year old rock salt in the USA (Mormile et al., 2003), which was deemed to resemble the well-characterized *Halobacterium salinarum* NRC-1 (see “*Halobacteria – Halophiles*”). From the Permian Salado formation in New Mexico, a novel strain, *Halosimplex carlsbadense*, was isolated (Vreeland et al., 2002).

Although the microbial content of ancient rock salt is low – estimates range from 1 to 2 cells/kg of salt from a British mine (Norton et al., 1993) to 1.3×10^5 colony forming units (CFUs) per kg of Alpine rock salt (Stan-Lotter et al., 2000), and up to 10^4 CFUs per g of Permian salt of the Salado formation (Vreeland et al., 1998), equivalent to a range of 1 pg to 10 μg of biomass per kg of salt – the reports showed that viable haloarchaeal isolates were obtained reproducibly by several groups around the world. The data support the hypothesis that the halophilic isolates from subterranean salt deposits could be the remnants of populations which inhabited once ancient hypersaline

seas; in addition, they provide strong evidence against the notion that the recovered strains could be the result of laboratory contamination, since the isolates were obtained independently from different locations.

The amplification of diagnostic molecules, such as the 16S rRNA genes of bacteria and archaea, by the polymerase chain reaction is now the standard method for obtaining material for subsequent nucleotide sequencing. For this technique it is not necessary to cultivate the microorganisms; the genes can be amplified by using DNA prepared from the material of interest. Analysis of dissolved Alpine rock salt with molecular methods was performed by extracting DNA and sequencing of 16S rRNA genes. The results provided evidence for the occurrence of numerous haloarchaea, which have not yet been cultured (Radax et al., 2001). Similarities of the 16S rDNA gene sequences were less than 90–95% to known sequences in about 37% of approximately 170 analyzed clones (Radax et al., 2001; Stan-Lotter et al., 2004); the remaining clone sequences were 98–99% similar to isolates from rock salts of various ages (McGenity et al., 2000) and to known haloarchaeal genera. In a similar experimental approach, using halite samples ranging in age from 11 to 425 millions of years, Fish et al. (2002) found haloarchaeal sequences and, in the older samples, also evidence for bacterial 16S rRNA genes which were related to the genera *Aquabacterium*, *Leptothrix*, *Pseudomonas*, and others. These data suggested the presence of a probably very diverse microbial community in ancient rock salt.

Long-term survival of cells

The reports cited above provide evidence that viable extremely halophilic archaea were isolated from salt sediments, which are thought to have been deposited about tens of thousands or even millions of years ago. The fluid inclusions in Permian rock salt were reported to contain cations and anions in a similar composition as today's seawater (Horita et al., 1991; Hay et al., 2006). While there is no direct proof that haloarchaea or other microorganisms have been entrapped in rock salt since its sedimentation, it would also be difficult to prove the opposite, namely that

masses of diverse microorganisms entered the evaporites in recent times (see also McGenity et al., 2000, for further discussion).

If a Permo–Triassic age is postulated for some of the haloarchaeal isolates and DNA signatures, then it becomes necessary to explain the biological mechanisms for such extreme longevity. Grant et al. (1998) discussed several possibilities, such as the formation of resting stages other than spores – since archaea are not known to form spores – or the maintenance of cellular functions with traces of carbon and energy sources within the salt sediments, which would imply an almost infinitely slow metabolism. At this time, there are no methods available to prove directly a great microbial age, whether it be a bacterium or a haloarchaeon. However, it can be shown, when simulating the formation of halite in the laboratory by drying salty solutions, which contained microorganisms that the cells accumulate within small fluid inclusions (Figure 3). The cells can be pre-stained with the fluorescent dyes of the LIVE/DEAD kit (Fendrihan et al., 2006), which provides information on the viability status of a cell (green fluorescence indicating viable cells); the procedure improves also the visualization of cells within crystals. The fluid inclusions were square or rectangular, as is common in the rectangular mineral halite, and the cells were rather densely packed within the fluid-filled spaces. From such experiments it appeared that the cells accumulated always in the fluid inclusions; there were no stained cells within the mineralic halite (Figure 3; Fendrihan et al., 2006). Suggestions have been made that fluid inclusions migrate within evaporites and thus, new nutrients might become accessible for the entrapped cells (McGenity et al., 2000).

Extraterrestrial halite and conclusion

Traces of halite were found in the SCN meteorites (named after the locations where they were found – Shergotty in India, Nakhla in Egypt, and Chassigny in France), which stem from Mars (Treiman et al., 2000). The Monahans meteorite, which fell in Texas in 1998, contained macroscopic crystals of halite, in addition to potassium chloride and water inclusions (Zolensky et al., 1999). Recently,

Deep Biosphere of Salt Deposits, Figure 3 Localization of pre-stained haloarchaea in fluid inclusions of artificial halite. Cells were stained with the LIVE/DEAD BacLight kit prior to embedding. Low (left panel) and high (right panel) magnification of *Halobacterium salinarum* NRC-1 cells. Cells were observed with a Zeiss Axioskope fluorescence microscope.

evidence for salt pools on the Martian surface was obtained (Osterloo et al., 2008). These results are intriguing – they suggest that the formation of halite with liquid inclusions could date back billions of years and occurred probably early in the formation of the solar system (Whitby et al., 2000). Could halophilic life have originated in outer space and perhaps traveled with meteorites, could haloarchaea have persisted in environments as they are found today on Mars?

Viable extremely halophilic archaea, representing novel strains, were isolated repeatedly from Permo–Triassic and other ancient salt sediments, suggesting their capacity for long-term survival under dry conditions. Together with the discovery of extraterrestrial halite it appears thus feasible to include into the search for life on other planets or moons specifically a search for halophilic microorganisms.

DEEP BIOSPHERE OF THE OCEANIC DEEP SEA

Kristina Rathsack, Nadia-Valérie Quéric, Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition and overview

Although used in many different ways, the term “biosphere” is principally defined either as zone in which life occurs, thereby overlapping the atmosphere, the hydrosphere, and the lithosphere, or as the entity of living organisms on Planet Earth. Both perceptions commonly focus on the Earth's near-surface environment, with all domains sharing solar energy used in the process of photosynthesis. The deep-sea realm takes a special position in this context, as deep-sea pelagic and the majority of benthic organisms live in the ocean's aphotic zone and inhabit the widespread abyssal plains, respectively. For a long time, their main food source has been considered to be based on particulate organic matter (POM) from the ocean's surface primary production and its sedimentation to abyssal depths (Gage and Tyler, 1991 and references therein, D'Hondt et al., 2002, 2004). With the discovery of “ocean vents” in the late 1970s (Corliss et al., 1979), this general perspective was broadened by the perception of the enormous potential of chemical energy through the reaction of seawater, rock material, and fluids rising from the Earth's interior. According to this concept of energy for life, the term ‘surface biosphere’ has been opposed to ‘sub-surface biosphere’ (also commonly found in literature as ‘deep biosphere’). Following this definition, the deep-seafloor with its highly diverse topography from heterotrophic to pure chemotrophic habitats has to be treated as a transition zone between both biospheres. Opposed to the “*deep hot biosphere*” (Gold, 1992), occurring by definition in oceanic as well as terrestrial subsurface environments, stands the “*deep cold biosphere*” as defined for permafrost sediments (Vorobyova et al., 1997) and ice cores from the depths of Lake Vostoc (Venter, 2001).

Life in the deep sea

Comprising approximately 65% of the Earth's surface, the deep-sea environment is characterized by hyperbaric, aphotic, and low-temperature conditions and highly

diverse seascapes. Canyons, seamounts, ridges, fractures, and trenches, but also biogeochemical oases such as cold seeps, mud volcanoes, carbonate mounds, brine pools, gas hydrates, hot vent systems, and deep-water coral reefs provide ample niches for a highly diverse pelagic and benthic deep-sea community (Tyler, 2003). It was only during the construction of the transoceanic telegraphic communication network that people realized the ocean's topographic alterations and astonishing depths. In 1861, the repair of an overgrown cable from 1,800 m water depth in the Mediterranean finally aroused the scientific community which by then adhered to Edward Forbes' theory on a completely ‘azotic’ zone below a water depth of 550 m. Though, 11 years had elapsed before the first global, scientific expedition onboard the “*Challenger*” (1872–1876) finally convinced people that a flourishing life in fact exists in the deep-sea realm. Numerous, further expeditions and a rushing development of technical facilities allowed deep-sea researches in 1960 to reach even the ocean's deepest surveyed point, the Challenger Deep at 10,911 meters below sea level (mbsl), located at the southern end of the Mariana Trench within the western Pacific Ocean (Piccard and Dietz, 1961). Since then, several studies on large-scale patterns and the zoogeographical origins of deep-sea organisms evidenced a high macrobenthic diversity (Gage and Tyler, 1991 and references therein). These organisms display a depth-dependent zonation as a result of basin age, deep currents (as barriers or dispersal), topographic boundaries, disturbance processes, and sedimentation in connection with depth-related environmental patterns (for review see Levin et al., 2001; Stuart et al., 2003). Macro- and meiofauna are losing importance with increasing water and sediment depth, whereas microorganisms like bacteria, archaea, and fungi account for up to 90% of the deep-sea benthic biomass (Pfannkuche, 1992). Sinking particles may carry large numbers of microorganisms from upper zones (10^8 – 10^{10} cells $m^{-2} d^{-1}$), inoculating deep marine surface sediments with an autotrophic and heterotrophic microbial community, as demonstrated by results from sediment traps (Turley and Mackie, 1995; Danovaro et al., 2000; Vanucci et al., 2001) or the deep-seafloor (Lochte and Turley, 1988).

Particulate organic matter (POM)

Due to the fact that most deep-sea benthic species are deposit feeders (Sanders and Hessler, 1969), the locally qualitatively and quantitatively, variable import of POM from the ocean's surface waters plays a crucial role for macro-, meio-, and microorganisms living in deep surface sediments (Goody and Turley, 1990). Mainly consisting of phytoplankton, marine snow, fecal pellets, (dead) zooplankton and molts, this material undergoes different steps of degradation during its passage from the photic, epipelagic (0–200 mbsl), through the mesopelagic (200–1,000 mbsl) to the actual deep-sea zones, in particular the bathypelagic (1,000–4,000 mbsl), the abyssal

Since then, several studies on large-scale patterns and the zoogeographical origins of deep-sea organisms evidenced a high macrobenthic diversity (Gage and Tyler, 1991 and references therein). These organisms display a depth-dependent zonation as a result of basin age, deep currents (as barriers or dispersal), topographic boundaries, disturbance processes, and sedimentation in connection with depth-related environmental patterns (for review see Levin et al., 2001; Stuart et al., 2003). Macro- and meiofauna are losing importance with increasing water and sediment depth, whereas microorganisms like bacteria, archaea, and fungi account for up to 90% of the deep-sea benthic biomass (Pfannkuche, 1992). Sinking particles may carry large numbers of microorganisms from upper zones (10^8 – 10^{10} cells $m^{-2} d^{-1}$), inoculating deep marine surface sediments with an autotrophic and heterotrophic microbial community, as demonstrated by results from sediment traps (Turley and Mackie, 1995; Danovaro et al., 2000; Vanucci et al., 2001) or the deep-seafloor (Lochte and Turley, 1988).

Particulate organic matter (POM)

Due to the fact that most deep-sea benthic species are deposit feeders (Sanders and Hessler, 1969), the locally qualitatively and quantitatively, variable import of POM from the ocean's surface waters plays a crucial role for macro-, meio-, and microorganisms living in deep surface sediments (Goody and Turley, 1990). Mainly consisting of phytoplankton, marine snow, fecal pellets, (dead) zooplankton and molts, this material undergoes different steps of degradation during its passage from the photic, epipelagic (0–200 mbsl), through the mesopelagic (200–1,000 mbsl) to the actual deep-sea zones, in particular the bathypelagic (1,000–4,000 mbsl), the abyssal

Desert Varnish. In arid environments such as Death Valley (California), rocks are covered with black opalescent desert varnish ([Figure 1](#)). Desert varnishes have been found in all continents, in locations such as the Gobi, Sonoran, Mojave, Namibian, Victorian, and Atacama

Desert Varnish, Figure 1 California desert varnish.

Deserts. The dark, lustrous coatings have attracted the interest of scientists for centuries. The German naturalist and explorer, Alexander Humboldt, observed desert varnish on a transatlantic expedition and questioned how this enigmatic feature would have formed. His contemporary, Darwin (1887), also engaged in the search for explanations for this unusual rock coating. To date, many other noteworthy scientists have examined desert varnish and have commented on its bulk chemistry, the arid conditions in which it forms and the concentration of manganese that makes it opaque and causes it to be black (cf. Perry et al., 2006, 2007; Perry, 1979; Staley et al., 1992).

Geochemists, planetary geologists, and microbiologists as well as archeologists are interested in desert varnish, as petroglyphs are incised in varnish coatings all over the world.

Yet, despite years of scientific effort, the origin of desert varnish is still shrouded in controversy. Most investigators have looked into biological causes where microbes create varnish and preferentially concentrate manganese relative to the local soils and rocks. However, more modern theories propose a nonbiological origin with sequential episodes of inorganic chemical reactions dominating formation processes.

“Desert varnish” is used here to define coatings that appear dark (reddish brown, chocolate, black, and blue-black). Reasons for not abandoning desert varnish as a term are both because of its historical use and because

it seems a most apt description for dark surfaces formed in subaerial conditions in hot and cold, and high and low elevation deserts. It must be emphatically stated that this definition of darkness is a macrovisual phenomenon. Close inspection of varnish coatings exposes the heterogeneity of the surface composition.

Desert varnish is a thin sedimentary deposit ($\sim <200\ \mu\text{m}$ thick) and under the microscope, its most notable feature is the presence of micron-sized layers. In typical geological thin sections ($30\ \mu\text{m}$ thickness) cut normal to the varnish surface the coatings are opaque. The making of a special ultra-thin section revealed the structure within the coating. This heterogeneity was first observed by Perry and Adams (1978) who showed that desert varnish coatings are composed of alternating light and dark layers. Silicon and oxygen are the primary elements in desert varnish, but oxides including aluminum, manganese, iron, titanium and magnesium are also important, and it is the variability in abundance of these oxides that creates the layers. Dark layers within varnishes are enhanced in manganese. Less laterally uniform variations in composition are also evident, and whole detrital grains can be embedded in varnish coatings. The thickness of layers is also variable and in three dimensions the growth of layers can lead to botryoidal (mounded) structures (Perry and Adams, 1978).

The black desert varnish is not the only type of rock coating draped in controversy; other coating types have also been observed in nature. Silica glazes are also found throughout the world and have been investigated in Hawaii (Curtiss et al., 1985; Farr and Adams, 1984), Morocco (Smith and Whalley, 1988), and Oregon (Farr, 1981). Their clear color is a result of not containing enough oxides to tint them black (manganese) or red (iron).

Recent investigations

It is now widely agreed that desert varnish and silica glazes are true coatings rather than weathering products of an underlying material. Consequently, some source materials for desert varnish must originate from external environments and are introduced by atmospheric transport. Dust can land on rock surfaces and its constituents take part in chemical reactions with some components becoming concentrated and adhered or “glued” together. Limited amount of water is essential for this process. Atmospheric deposits of trace elements are also deposited and have become part of varnish coatings (Thiagarajan and Lee, 2004). Importantly, the chemical composition of desert varnish necessitates that unused elements and materials need to be removed in a never-ending interchange that allows for the concentration and formation of mineral components.

In the past, this enigmatic coating has been ascribed to the action of bacteria or fungi on desert rock surfaces. Microbes are thought to be pervasive in all environments on Earth, and researchers have actively sought a causative link to desert varnish. However, ongoing Martian analog studies in extreme arid conditions such

as the Atacama Desert show that bacteria are rarely present on rock surfaces (Jones, 1991). The black top coatings were attributed to biological action, and early investigators speculated that the manganese oxidizing bacteria concentrated the manganese oxides on the top but did not grow as readily underneath rocks. Primarily, these investigations used culture-based studies of microbes, both bacterial and fungal (Hungate et al., 1987). The emphasis was on an exhaustive search for manganese and iron oxidizing microbes. The manganese and iron were thought to have been absorbed from dust by the bacteria and oxidized during biochemical reactions over thousands of years (Dorn and Oberlander, 1981). According to conventional thought, the silicate particles were also obtained from the atmosphere and cemented together by oxides produced by bacteria. Yet, biological mechanisms remain unsatisfactory, and no viable hypothesis has been presented that provides an explanation for key varnish features such as its hardness, a mechanism for binding the heterogeneous components together, a means of producing the lamellar and botryoidal morphologies, and its slow rates of formation (Liu and Broecker, 2000).

While cultures of bacteria were obtainable from the surfaces of varnish-coated rocks, a direct look at those surfaces using electron microscopes, after fixing the surfaces in order to preserve any biology present, rarely revealed the presence of bacteria. This was noted by Jones (1991) in the Atacama and Smith and Whalley (1988) in the Atlas Mountains of Morocco and Perry et al. (2007) in the Mojave Desert.

Incomplete remains of organisms are, however, entombed in desert varnish coatings. The first examination of organic molecules being trapped or complexed in varnish coatings was published by Perry et al. (2003). Other organic compounds may also make a C–O bond or be entombed in the disordered silica matrix. Following the discovery of amino acids, DNA was found using molecular techniques by Perry et al. (2004) and Kuhlman et al. (2006); also several polymorphic compounds are present in varnishes (Perry et al., 2007) and lipids (Schelble et al., 2001). These findings suggest that varnish coatings preserve past biology and as discussed later, may be an important recorder of contemporaneous life in the local environment.

Several investigative techniques including, high resolution electron microscopy has revealed that silica as opal, not clays or metal oxides, is probably the most important mineral present in desert varnish. When there is moisture, depressions on rock surfaces form small dimples to larger indentations in which silicic acid may form, leaving varnish structures in the depressions. Evaporation of water eventually causes concentrations to increase and, eventually, condensation of the silicic acid occurs to produce a gel. During gel formation, surface detrital material and organic compounds are incorporated, and when the gels are dried and dehydrated the components are entombed in a lustrous rock coating (Perry et al., 2006, 2007). Evidence of the occasional action of water is forthcoming from analyses which indicate that despite being formed

in arid environments, the coatings have been shown to contain up to 9% water (Perry, 1979). This in itself represented a conundrum until the hypothesis of water-rich silica was put forth.

We can then conclude that silica in desert varnish and silica glazes and even hot-spring silica-rich sinters (see Chapter *Sinter*) are made by similar processes (Phoenix et al., 2006; Perry and Lynne, 2006). Desert varnish then can be thought of as a silica glaze enriched in oxides.

Hypotheses of formation must stand up to scientific testing, and it has often been said that if we could only make a synthetic coating in the laboratory that we must inevitably understand how coatings are made in nature. Laboratory experiments support the role of silica polymerization. Surprisingly, it turns out to be a relatively easy process to make coatings in the laboratory (Perry et al., 2005). Conversely, several attempts to make coatings using microbes produced no coatings further supporting nonbiological explanations for desert varnish. It cannot be ignored, however, that biological organic compounds may effect the chemical formation of coatings when they are present.

Conclusions

Recent work then indicates that biology is not required for desert varnish formation and the source of the organic components is from outside sources landing on the surface. Importantly, however, the accumulation of environmental products in desert coatings preserves a biological, climatological, and environmental record. Keeping a chronicle of past life is not only of interest on Earth, but similar process may also be in portent on other planets such as Mars.

Recently, camera images from the Mars Pathfinder landing site have strongly suggested the presence of desert varnish on many Martian rocks (Murchie et al., 2004). Angular, equant, and tabular rocks and large boulders display spectral characteristics suggesting varying levels of ferric minerals. These minerals form part of a desert varnish-like coating that may have formed in the presence of thin films of water when Mars had a moist climate than the present-day climate.

If silica exists in desert varnish-like coatings on Mars, as on Earth, then it may contain chemical signatures of previous life (Perry and Hartmann, 2006). It is possible that on Mars the earliest formed layers in any stromatolite-like sequence may have recorded a wetter and more biologically amenable Martian environment. Moreover, it is likely that Martian desert varnish would be a better preserver of organic matter than its Earth counterpart (Perry and Sephton, 2006). The current Martian environment is much colder and drier than that on Earth. Martian desert varnish records may also extend further back in time. On Earth, desert varnish is a relatively recent rock coating generated in time periods commonly less than 100,000 years; older examples are removed by physical and chemical weathering. Evidence of ancient surfaces and events on Mars suggests that both physical and chemical weathering are less aggressive than on our planet.

DETACHMENT

Definition

Detachment refers to the release and transport of microbial cells and their associated extracellular polymeric substances from an attached microbial biofilm to the fluid compartment bathing the film (Stewart, 1993).

Together with microbial attachment and growth, detachment is a primary process that balances biofilm accumulation and activity. Detachment processes control the (re-)dispersal of cells from biofilms into the planktonic community and hence are crucial for bacterial expansion and the exploration and colonization of new niches (Toutain et al., 2004). Bryers (1988) distinguished several categories of detachment processes: (i) *Erosion* is a more or less continuous removal of individual cells or small groups of cells resulting from the moving fluid in contact with the surface of the biofilm, whereas (ii) *abrasion* is caused by the collision of particles. (iii) *Sloughing* refers to the release of relatively large particles of biomass, whose size is comparable to or greater than the thickness of the biofilm itself. Furthermore, (iv) *predator grazing* may be considered as another form of detachment process.

DETACHMENT

Definition

Detachment refers to the release and transport of microbial cells and their associated extracellular polymeric substances from an attached microbial biofilm to the fluid compartment bathing the film (Stewart, 1993).

Together with microbial attachment and growth, detachment is a primary process that balances biofilm accumulation and activity. Detachment processes control the (re-)dispersal of cells from biofilms into the planktonic community and hence are crucial for bacterial expansion and the exploration and colonization of new niches (Toutain et al., 2004). Bryers (1988) distinguished several categories of detachment processes: (i) *Erosion* is a more or less continuous removal of individual cells or small groups of cells resulting from the moving fluid in contact with the surface of the biofilm, whereas (ii) *abrasion* is caused by the collision of particles. (iii) *Sloughing* refers to the release of relatively large particles of biomass, whose size is comparable to or greater than the thickness of the biofilm itself. Furthermore, (iv) *predator grazing* may be considered as another form of detachment process.

Important factors controlling and/or inducing biofilm detachment include the activity of matrix-degrading enzymes, microbially generated gas bubbles, nutrient levels, microbial growth status, availability of multivalent cross-linking cations, fluid shear stress, and contact attrition (Hunt et al., 2004). In addition, there is increasing evidence that bacterial biofilms may actively regulate dispersion processes using cell-to-cell signaling (quorum-sensing). Dissolution of the biofilm matrix and release of bacteria are hypothesized to be triggered when a signal molecule, i.e., an excreted bacterial metabolite, accumulates to a threshold concentration (Hunt et al., 2004; Waters and Bassler, 2005).

Bacillariophyta

Definition

Diatoms (Chromalveolates supergroup, photosynthetic Stramenopiles, Bacillariophyta) are unicellular or colonial eukaryotic algae with unique cell walls composed of amorphous silica and consisting of two parts.

The diatoms (Bacillariophyta) represent an extremely diverse and successful lineage of photosynthetic Stramenopiles (Chromalveolates) with cell walls composed of amorphous silica and consisting of two parts,

termed frustules, as their most striking feature. The diatoms are of unicellular organization, but some form colonies. The diatom plastids are derived from red algal secondary symbiosis and are golden brown due to the high concentration of the carotenoid fucoxanthin. Diatoms are exceedingly abundant and thought to be the most important group of eukaryotic phytoplankton, responsible for approximately 40% of marine primary productivity (Falkowski et al., 1998). Their high abundance coupled with the resistance of diatom frustules to dissolution in normal waters has resulted in massive sedimentary accumulation and a significant fossil record.

Cell structure

Frustule: The diatom frustule is a highly patterned external wall composed of amorphous silica $[(\text{SiO}_2)_n(\text{H}_2\text{O})]$. Silica is often plentiful in natural waters (it is the second most abundant element in the Earth's crust) and is an energetically inexpensive source of wall material (Falkowski and Raven, 1997). The diatom frustule is constructed of two almost equal parts, termed valves, with the smaller valve (hypotheca) fitting into the larger (epitheca). Each theca is typically composed of two parts: the valve (which forms the larger outer surface) and a girdle (circular bands of silica attached to the edge of the valve). The frustule is present in all living diatoms, except following secondary loss in endosymbiotic diatoms living in some dinoflagellates (Tamura et al., 2005) and some foraminifera (Lee and Correia, 2005). Owing to their requirement for silica for cell wall biogenesis, the diatoms play a key role in the biogeochemical cycling of silica (Tréguer et al., 1995). Diatom frustule walls predominate in the sediments of the ocean floor, thus making the diatoms serious players in ocean biogeochemistry over geologically significant timescales (Kemp et al., 2000). Analysis of diatom frustule containing sediments can provide information on past environmental conditions (e.g., Reavie et al., 1998). Fossil diatom frustule deposits are even mined as diatomaceous earth and commercially used as filter material, mild abrasives, and absorbent or insulation materials (Lee, 2008). The precise method of frustule formation is still not fully understood but most models propose the formation of a matrix of organic fibrils and microtubules onto which the silica is deposited. More recently, Sumper and Kröger (2004) have suggested that silica formation takes place in intracellular compartments termed silica deposition vesicles (SDVs).

Two major categories of frustule shapes can be distinguished, that is, discoid or cylindrical cells with radial symmetry in valve view (centric diatoms) and elongated cells with a more or less bilateral symmetry (pennate diatoms). Some pennate diatoms have slits in their frustule that extends between both cell ends, the raphe system. Such diatoms are known as raphid diatoms and they possess the ability to accomplish rapid gliding motility. Other pennate diatoms lacking raphes are nonmotile and termed araphid diatoms (Round et al., 1990; Graham et al., 2009). The motive force for motility may come from

system of large fossils is excellently preserved (Franzen, 1994). Fundamental studies on biofilm soft-tissue relationship were carried out by Richter (1994) and Liebig (1997). Another intriguing example is the “soft-tissue” preservation in dinosaur bones (Kaye et al., 2008). Kaye and coworkers have found microbially altered soft tissue in a dinosaur bone and they give a critical explanation of this fact. Within their paper they discuss the processes of tissue preservation and also demonstrate the importance of recent microbial biofilm invasion and late diagenetic alteration of primarily formed pyrite framboids. The clou of this investigation is also that there is no real soft-tissue preservation – however, preserved biofilms cast the former tissue and give an idea about the original structures.

All “Hautschatten” soft-tissue preservations are probably preserved lithified biofilms and not real soft tissues.

Conclusion

Biofilms play a significant role in suboxic and anaerobic milieus preserving soft tissue remains. The body outline of dead organisms is exactly traced by the margins of the mineralised biofilms and give a perfect image of the entire fossil. These structures are often called after the German word “Hautschatten”-perservation and is commonly found under black shale condition.

BIOGEOCHEMICAL CYCLES

A biogeochemical cycle defines the pathways by which chemical elements occurring in organisms are cycled between different living and nonliving compartments on the Earth (e.g., biosphere, atmosphere, hydrosphere, geosphere, etc.). Typical driving forces of a biogeochemical cycle are the metabolisms of living organisms, geological processes, or chemical reactions. For specific reading on major biogeochemical cycles, please refer to “[Carbon Cycle](#),” “[Nitrogen](#),” “[Sulfur Cycle](#),” “[Phosphorus](#),” “[Phosphorites](#).”

BIOLOGICAL CONTROL ON DIAGENESIS: INFLUENCE OF BACTERIA AND RELEVANCE TO OCEAN ACIDIFICATION

Fred T. Mackenzie¹, Andreas J. Andersson²

¹University of Hawaii, Honolulu, HI, USA

²Bermuda Institute of Ocean Sciences, Ferry Reach, St. George's, Bermuda

Introduction

Soon after carbonate mineral particles are deposited, a series of chemical, physical, and biological processes start that can significantly alter their mineralogy, isotopic composition and chemistry, and the fabric of the accumulating sediment. These processes include dissolution and precipitation reactions, abrasion, and transport, and

ingestion and boring by organisms. The processes occurring after deposition fall into the category of diagenesis. In particular, carbonate sediments consisting of the minerals low (<4 mol% MgCO_3) and high (>4 mol% MgCO_3) biogenic and inorganic magnesian calcite and aragonite and organic matter deposited in shallow waters are repeatedly deposited, resuspended, and then deposited again during periods of elevated turbulence, which are common especially during storms. Consequently, carbonate minerals may be subjected to several depositional environments before being permanently buried in a sediment. The study of carbonate diagenesis is further complicated by the fact that significant amounts of shallow-water carbonates are commonly associated with reefs, for which traditional models of sediment diagenesis are not always appropriate.

Soon after deposition, chemical and physical changes occur in carbonate sediments as a result of a myriad of diagenetic processes. Among the most important are dissolution-precipitation reactions and major alterations of pore water chemistry by bacterially mediated oxidation of organic matter. These changes generally occur most rapidly in the upper few to tens of centimeters of sediment. It is this topic that is most fully addressed in this article. In addition, transport within the sediment of both solid and dissolved components is also of fundamental importance in diagenesis. It can be caused by physical stirring resulting from the movement of infaunal organisms (e.g., worms, bivalves, shrimp), and is called bioturbation. Closely associated with bioturbation is bioirrigation, which is a result of organisms pumping water through their burrows. Deeper within the sediment and thus later in its history, advection of pore water and molecular diffusion in pore water are generally the dominant transport processes.

The diagenetic equation

Since the early 1960s, considerable effort has gone into modeling the diagenesis of sediments. A central theme of most models is that diagenetic change results from the sum of transport and chemical and biological reactions of various types. Diagenetic models can be divided into those assuming constant conditions (steady-state models) and those taking into account factors that may vary with time (e.g., temperature, salinity, material input rates, water depth). The primary idea in the steady-state models is that a property in the sediment, at a given depth below the sediment-water interface, is time-independent (Figure 1). Thus, if one were to measure the pore water acidity (pH) in a sediment at 20 cm depth and come back 10 years later and again measure the pH at the 20 cm depth, it would be the same. This statement would be true even though the sediment was not physically the same at the 20 cm depth because of deposition during the intervening 10 years.

The general diagenetic equation from which many important models have been derived (e.g., Berner, 1980) is:

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 1 Diagram illustrating under steady-state (constant) conditions how a property such as hydrogen ion concentration varies with depth as the sediment column accumulates. Note that a property at fixed depth x_1 does not change in magnitude as the sediment accumulates.

$$(\partial C_i / \partial t)_x = -\partial F_i / \partial x + \sum R_i \quad (1)$$

where C_i = concentration of solid or liquid component i in mass per unit volume of total sediments (solids plus pore water); F_i = flux of component i in terms of mass per unit area of total sediment per unit time; and R_i = rate of each diagenetic chemical, biochemical, and radiogenic reaction affecting i in terms of mass per unit volume of total sediment per unit time. An example of application of this equation would be the change in hydrogen ion concentration (pH) with time at a given depth in a sediment due to diffusive transport and the dissolution of calcium carbonate in the sediment. For a steady-state condition, Equation 1 is set equal to 0, because at a given depth x , the hydrogen ion concentration does not change with time. Steady-state models are generally more amenable to a mathematical solution than non-steady-state models. However, diagenesis in many shallow-water carbonate sediments is significantly influenced or even dominated by non-steady-state processes.

Dissolution of carbonates

Continental shelves and slopes comprise about 20% of the Earth's surface, and contain more than half of the sediments in the ocean. Recent estimates of marine carbonate burial rates indicate that between 35% and 70% of Holocene carbonate deposition has taken place on continental shelves and today's production of shallow-water biogenic carbonate ("calcareous") skeletons and tests represents about 28% of the total carbonate produced in the world's oceans.

A substantial fraction (>50%) of shallow-water produced CaCO_3 is at present time permanently buried in the sediments. In contrast, most of the CaCO_3 produced in the open ocean mainly by planktonic organisms such as coccolithophorids, forams, and pteropods dissolves before it reaches the ocean floor. As much as 50–90% of the material may dissolve in the upper 1,000 m owing to microbial decomposition of organic matter creating microenvironments corrosive to CaCO_3 particles. Typical examples of such environments include inside the guts of zooplankton or within aggregates of CaCO_3 and organic material referred to as “marine snow.” Carbonate material making it past the depth of the saturation horizon, the thermodynamic equilibrium boundary between the forward and backward reactions of precipitation and dissolution, will consequently become subject to dissolution regardless of the activity of microbes and the formation of microenvironments.

Since most shallow-water environments (coastal zone, continental shelf, banks, reefs, etc.) at present time are immersed in seawater supersaturated with respect to calcite, aragonite, and most Mg-calcite phases, dissolution of sedimentary CaCO_3 minerals in these environments is completely driven by microbially mediated processes associated with oxidation of organic material in the pore water-sediment system or boring autotrophic or heterotrophic microorganisms referred to as endoliths. In the presence of oxygen, the extent of CaCO_3 dissolution is almost completely controlled by the amount and the extent of organic matter decomposed or respired, but under anoxic conditions, oxidation of organic matter accompanied by reduction of sulfate can produce radically different

results. Most studies of the impact of chemical diagenesis on the carbonate chemistry of anoxic sediments have focused primarily on the fact that sulfate (SO_4^{2-}) reduction results in the production of alkalinity (mostly dissolved bicarbonate [HCO_3^-], carbonate [CO_3^{2-}] and carbonic acid [H_2CO_3] and CO_2 chemical species), which can cause precipitation of carbonate minerals (e.g., Berner, 1971). The reduction of the sulfate is promoted by bacteria, particularly *Desulfovibrio desulfuricans*, splitting the sulfur–oxygen bond and leading to the accumulation of dissolved chemical species of reduced sulfur (mainly H_2S and HS^- ; these sulfur species may contribute to the total alkalinity of the pore waters) in the pore waters and in sediments containing iron as ferrous sulfide minerals (mainly pyrite, “fool’s gold,” FeS_2) and free solid sulfur. Although the reaction is complex, this process can be schematically represented, using the average composition of organic matter of phytoplankton as substrate material, as:

which results in the commonly observed decrease in sulfate ion, and pH (measure of hydrogen ion concentration, H^+), and increase in total alkalinity, hydrogen sulfide (H_2S), phosphate (PO_4^{3-}), ammonia (NH_3), and total dissolved inorganic carbon (DIC) in sediment pore waters with increasing depth below the sediment–water interface.

During the early stages of sulfate reduction (~2 to 35%) (Figure 2), this reaction may not cause precipitation,

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 2 The saturation state with respect to aragonite (Ω aragonite) of marine pore waters as a function of the amount of sulfate reduced to sulfide based on the model of Ben Yakoov (a). Saturation state with respect to calcite (Ω calcite) as a function of depth as observed in Mangrove Lake, Bermuda sediment pore waters. (From Morse and Mackenzie, 1990.)

but rather results in undersaturation conditions with respect to carbonate minerals because the impact of lowered pH (increasing H^+) has a larger negative effect on the total alkalinity than the positive effect on this chemical property arising from reduction of sulfate. Carbonate ion activity decreases rapidly as it is "titrated" by CO_2 from organic matter decomposition abetted by bacteria leading to a decrease in pore water saturation state. This process is evident in observational data for Fe-poor shallow water carbonate sediments from the Bahamas and has been confirmed in recent studies of sediments from Florida Bay, in the Checker Reef of Kaneohe Bay, Oahu, Hawaii, and in organic-rich sediments of Mangrove Lake, Bermuda (Morse and Mackenzie, 1990) and elsewhere. In Mangrove Lake, it was shown based on model calculations that the degree of undersaturation of anoxic pore waters with respect to carbonate mineral compositions can depend significantly on the carbon to nitrogen ratio (C/N) of the labile organic matter undergoing bacterial oxidation in the sediment pore water (Figure 3).

This sulfate reduction reaction in anoxic carbonate sediments has potential importance for carbonate dissolution in shallow-water, marine environments, but its global significance remains a question. An observation of interest is that even complete sulfate reduction can return the saturation state of the pore water only to about half of its original value. Thus, the sulfate reduction reaction by itself may not promote carbonate precipitation as total alkalinity increases and partial sulfate reduction may result in carbonate dissolution. The combination of the sulfate reduction reaction and reactions primarily with iron and

manganese oxide minerals in the sediments can lead to significant calcium carbonate precipitation. This type of net process can be represented schematically as (where CH_2O is a simplified formula for organic matter):

Reaction 3 results in the pH of the waters, in the absence of carbonate precipitation, being buffered at higher pH values. It is, therefore, reasonable to expect that the effectiveness of sulfate reduction in producing carbonate dissolution or precipitation may depend in part on the availability of reactive iron. This conclusion has been demonstrated in a study of the pore water geochemistry of aluminosilicate and carbonate-rich sediments from Kaneohe Bay, Oahu, Hawaii. The aluminosilicate sediments contain abundant pyrite whereas the pyrite content of the carbonate sediments in the bay is low. Pore waters collected from the aluminosilicate sediments have higher pH values than those collected from the carbonate-rich sediments. This observation is a result of the pH values in the pore waters of the aluminosilicate sediments being buffered at higher values than those for carbonate sediments because of Reaction 3 (Mackenzie et al., 1981).

There are several processes that have been identified that can cause undersaturation of pore waters with respect to carbonate minerals, in addition to the previously discussed undersaturation conditions that may result during the early stages of sulfate reduction. These are early post-death microenvironments within organisms, oxidation of organic matter by processes preceding sulfate reduction, and oxidation of sulfides. In addition, both autotrophic and heterotrophic endoliths actively penetrate carbonate substrates by creating corrosive conditions with respect to these mineral phases. These processes commonly will be most important near the sediment–water interface. The most important process occurring prior to the onset of bacterial sulfate reduction is extensive organic matter degradation due to bacterially mediated oxygen reduction, a process important in both shallow-water and deep-sea carbonate sediments. The influence of benthic bacterial activity under aerobic conditions on carbonate mineral dissolution was nicely demonstrated by Moulin et al. (1985) for pore waters from sediments of the Gulf of Calvi, Corsica. Under aerobic conditions, the oxidation of organic matter may be written:

and if carbonate minerals were to dissolve because of the CO_2 produced by organic matter decomposition, then the reaction:

The overall net Reaction of 4 + 5 is:

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 3 Diagram illustrating how the C/N ratio of the organic matter deposited influences the saturation state with respect to aragonite ($\log(IAP/Karag)$; 0.0 = saturation) of the pore waters of Mangrove Lake, Bermuda organic-rich sediments. The saturation state is shown as a function of the amount of dissolved inorganic carbon (DIC) added to the pore waters from the oxidation of organic matter by aerobic oxygen consumption and anaerobic sulfate reduction processes. (From Morse and Mackenzie, 1990.)

Reaction 6 is possible only if the pore waters are undersaturated with a carbonate phase, and there are no other competing reactions, like significant ammonia release from decaying organic matter, to increase pore water saturation state. **Figure 4** shows the increase in total alkalinity versus increase in total CO_2 ($\Delta\Sigma\text{CO}_2$) as observed in shallowly buried pore waters in the Gulf of Calvi *Lithothamnion* sp. algal-rich sediments and in low and high magnesian calcite- and aragonite-rich sediments from Mangrove Bay, Bermuda. The slopes of the regression lines for the relationships are close to 1. The slope indicates that **Reaction 6** most likely gives rise to the increased total alkalinity observed in these pore waters; that is, the H_2CO_3 produced by organic matter oxidation is stoichiometrically utilized in dissolution of a carbonate mineral phase in the sediment. Close inspection of the regression line for the Gulf of Calvi sediments in **Figure 4** shows that it does not pass through the origin. This is because about 0.1 mmol kg^{-1} of H_2CO_3 has been added to the pore waters from aerobic bacterial respiration prior to carbonate dissolution. This initial input of H_2CO_3 lowers the saturation state of the shallowly buried pore waters to that required for carbonate mineral dissolution. These pore water observations have been confirmed in experiments using a biological reactor,

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 4 Increase in total alkalinity (ΔA_t , change in sediment pore water total alkalinity from that of overlying water column) and total DIC ($\Delta\Sigma\text{CO}_2$, change in sediment pore water total DIC from that of overlying water column) in pore waters of Gulf of Calvi, Corsica (insert, Moulin et al., 1985), and Mangrove Bay, Bermuda. Notice the slope of the lines of nearly 1 as predicted from **Reaction 6**. At zero total alkalinity the total DIC is not zero due to the addition of dissolved carbon species to the pore water column from the biological, mainly bacterial, remineralization of organic matter at very shallow depths (several centimeters) in the sediments above the depth, at which the waters become undersaturated with some magnesian calcite compositions and carbonate minerals dissolve with increasing depth.

and from solid phase mineralogical studies. High magnesian calcites are dissolved preferentially in these sediments, although the sediment contains a mixture of nearly pure calcite, aragonite, and magnesian calcites with up to 20 mol% MgCO_3 . In the Gulf sediments composed principally of the red alga *Lithothamnion* sp., this early diagenetic reaction has resulted in dissolution of 75% of the carbonate initially deposited. Furthermore, in the case of the study of Mangrove Bay, the pore waters were sampled every few hours during a complete, 24 h, diel cycle. The trend and relationship between changes in total alkalinity and total DIC are essentially the same as observed in the sediments of Gulf of Calvi. In addition, sea grasses, such as *Thalassia*, which covers vast areas of the bottom in Mangrove Bay probably enhances carbonate dissolution in these sediments by releasing oxygen through its roots and rhizomes into the sediments that consequently enhances decomposition of organic matter and production of H_2CO_3 . Evidence from the Bahamas bank has clearly demonstrated enhanced calcium carbonate dissolution owing to this process (Burdige and Zimmerman, 2002).

Other reactions of less importance than those above leading to undersaturated conditions with respect to calcium carbonate near the sediment–water interface include nitrate reduction and fermentation (e.g., Aller, 1980). Such reactions may also be important near the sediment–water interface of continental shelf and slope sediments, where bioturbation and bioirrigation can result in enhanced transport of reactants. Generally, as the water depth increases over continental slope sediments, the depths increase within the sediment at which significant sulfate reduction and reactions other than sulfate reduction influence carbonate chemistry.

Carbonate dissolution and ocean acidification

Future increases in atmospheric CO_2 owing to human activities, such as burning of fossil fuels and land-use changes, result in increased uptake of part of this CO_2 by ocean surface seawater and formation of carbonic acid. As the term implies, dissociation of carbonic acid produces hydrogen ions, which results in increasing acidity and decreasing pH of seawater and therefore the name ocean acidification. Surface seawater pH has already decreased by approximately 0.1 pH units since the onset of the Industrial Revolution and is anticipated to decrease by another 0.2–0.3 pH units by the end of the twenty-first century (e.g., Caldeira and Wickett, 2003). Oceanic uptake of CO_2 also produces an increase in the seawater concentration of bicarbonate ions (HCO_3^-) and a decrease in the carbonate ion concentration (CO_3^{2-}). As a consequence, the saturation state with respect to calcium carbonate minerals (Ω), which is determined by dividing the in situ ion concentration product of calcium and carbonate ions by an experimentally determined solubility product ($\Omega = [\text{Ca}^{2+}][\text{CO}_3^{2-}]/K_{sp}^*$), will decrease. A lower carbonate saturation state of surface seawater implies that the initial composition of marine sediment pore waters will be closer to undersaturation with

respect to carbonate minerals, and thus, microbial decomposition of less organic material is required to produce undersaturated conditions and subsequent dissolution of carbonate mineral phases in the pore water–sediment system. Furthermore, while most shallow-water environments at present time are supersaturated with respect to calcite, aragonite, and most Mg-calcite phases (in general, Mg-calcite containing 8–12 mol% MgCO_3 or more is more soluble than both calcite and aragonite), surface seawater in high and intermediate latitude environments could become undersaturated with respect to most Mg-calcite phases and even aragonite during the present century. Consequently, as a result of human-induced ocean acidification, dissolution of carbonate minerals and sediments in shallow-water ocean environments is most likely to increase.

Increased dissolution of calcium carbonate minerals and sediments owing to human-induced ocean acidification will most likely occur selectively according to mineral stability. This could lead to a change in the average mineral composition of contemporary carbonate sediments in favor of stable mineral phases such as calcite and low Mg-calcite phases over metastable phases such as aragonite and high Mg-calcite. Although such a transition is slow relative to the rate at which seawater chemistry is changing owing to human activities, evidence for increasing carbonate dissolution and changing sediment composition exists based on numerical model simulations, saturation, and dissolution experiments, and mesocosm experiments, as well as from observations from natural environments. One such environment is Devil's Hole, located within Harrington Sound, Bermuda. During summertime, the water column of Devil's Hole becomes significantly stratified owing to the exponential decrease of solar irradiance as a function of depth. Organic matter produced in the surface mixed layer sinks and is decomposed by microbes in the subthermocline layer. As a consequence, the CO_2 , pH and the seawater saturation state with respect to carbonate minerals in this layer reach values typically not observed for most shallow-water environments today, but similar to values anticipated during the next several decades of the twenty-first century as a result of ocean acidification. In spite of significant production of fine grained Mg-calcite minerals throughout Harrington Sound, for example, by coralline algae, forams, and echinoderms, as well as the abundant occurrence of these mineral particles in sediments located at depths above the thermocline, little evidence exists for their presence in the sediments of Devil's Hole. These mineral phases are most likely selectively dissolved, a conclusion that is also supported by observed changes in seawater carbonate chemistry in the subthermocline layer in Devil's Hole (Figure 5; Neumann, 1965; Andersson et al., 2007).

In addition to the chemical changes imposed on surface seawater owing to rising atmospheric CO_2 , future dissolution of shallow-water carbonate minerals could also increase owing to increased deposition and subsequent increased microbial decomposition of organic matter in marine coastal sediments. Human activities on land have

Biological Control on Diagenesis: Influence of Bacteria and Relevance to Ocean Acidification, Figure 5 (a) Partial pressure of CO_2 (pCO_2) in the water column of Devil's Hole, Harrington Sound, Bermuda. The pCO_2 of the subthermocline layer (gray) is significantly higher than anticipated from equilibrium with the atmosphere owing to microbial decomposition of organic matter. As a result, calcium carbonate minerals are selectively dissolved, which is demonstrated in (b) and (c). The former shows changes in salinity normalized ($S = 36$) calcium concentration ($\Delta n[\text{Ca}^{2+}]$) as a function of total alkalinity ($\Delta n\text{TA}$) in the subthermocline layer. The observed relationship clearly demonstrates that carbonate dissolution is taking place and the slope of a best fit line (0.44) suggests that the average composition of the dissolving phases has an Mg-content of 12 mol% MgCO_3 . (c) Relative weight percent high Mg-calcite as a function of sediment grain size and depth in Devil's Hole and Harrington Sound. For small grain sizes ($<62 \mu\text{m}$), the high Mg-calcite content decreases as a function of depth. The figure has been compiled based on data from Neumann (1965), Balzer and Wefer (1981), and Andersson et al. (2007).

significantly increased the amount of organic matter transported via rivers and runoff to the global coastal ocean relative to preindustrial conditions, and the total amount is expected to continue to increase with increased

deposition of this material to the sediments. Furthermore, input of nutrients to the global coastal ocean region have also significantly increased, which may stimulate increased production of organic matter and subsequent deposition of this material to the sediments within this region. As long as surface seawaters are supersaturated with respect to most carbonate phases, microbial decomposition of organic material is the main driver of carbonate dissolution. Consequently, even if the organic material deposited to the sediment–water remained constant, but the microbial activity increased, for example, owing to increasing temperature, carbonate dissolution would also increase. For the next several decades, human activities are likely to continue to lead to acidification of surface seawater and continuous increases in the amount of organic material being deposited to shallow-water sediments, and concurrently with increasing atmospheric concentrations of CO₂, surface and sea surface temperatures are likely to increase with potential increases in microbial and endolithic activity. As a result, dissolution of calcium carbonate minerals, particularly in coastal ocean environments, probably will increase due to all of these forcings. It is possible that under a business as usual scenario of fossil fuel CO₂ emissions, the production of carbonates in the global coastal ocean will be exceeded by their dissolution by year 2150 or earlier.

Summary

Diagenesis refers to those physical, chemical and biological processes that alter the original physical and chemical characteristics and properties of minerals and sediments. Calcium carbonate minerals constitute a substantial fraction of shallow-water sediments and may be subject to significant diagenetic alterations after deposition including dissolution and precipitation reactions. These reactions are largely mediated by microbial processes including oxidation of organic matter under both oxic and anoxic conditions as well as by endoliths, which actively penetrate carbonate substrates. The extent of calcium carbonate dissolution is to a large degree controlled by the amount of organic matter decomposed. Carbonate dissolution is likely to increase in the future in response to human-induced ocean acidification arising from the burning of fossil fuels, but also due to increased riverine transport of organic matter and nutrients to the coastal ocean, enhanced production in situ of organic matter in coastal waters, and subsequent deposition and microbial decomposition of the organic matter in marine sediments.

BIOLOGICAL VOLCANIC ROCK WEATHERING

Charles S. Cockell
 Open University, Milton Keynes, UK

Definition

The biologically induced breakdown of volcanic rocks, including crystalline rocks and glasses.

Volcanic rock weathering and global processes

The weathering of volcanic minerals is known to make a significant contribution to the global silicate weathering budget (Dessert et al., 2003), thus influencing carbon dioxide drawdown and climate control, since carbon

Important factors controlling and/or inducing biofilm detachment include the activity of matrix-degrading enzymes, microbially generated gas bubbles, nutrient levels, microbial growth status, availability of multivalent cross-linking cations, fluid shear stress, and contact attrition (Hunt et al., 2004). In addition, there is increasing evidence that bacterial biofilms may actively regulate dispersion processes using cell-to-cell signaling (quorum-sensing). Dissolution of the biofilm matrix and release of bacteria are hypothesized to be triggered when a signal molecule, i.e., an excreted bacterial metabolite, accumulates to a threshold concentration (Hunt et al., 2004; Waters and Bassler, 2005).

Bacillariophyta

Definition

Diatoms (Chromalveolates supergroup, photosynthetic Stramenopiles, Bacillariophyta) are unicellular or colonial eukaryotic algae with unique cell walls composed of amorphous silica and consisting of two parts.

The diatoms (Bacillariophyta) represent an extremely diverse and successful lineage of photosynthetic Stramenopiles (Chromalveolates) with cell walls composed of amorphous silica and consisting of two parts,

termed frustules, as their most striking feature. The diatoms are of unicellular organization, but some form colonies. The diatom plastids are derived from red algal secondary symbiosis and are golden brown due to the high concentration of the carotenoid fucoxanthin. Diatoms are exceedingly abundant and thought to be the most important group of eukaryotic phytoplankton, responsible for approximately 40% of marine primary productivity (Falkowski et al., 1998). Their high abundance coupled with the resistance of diatom frustules to dissolution in normal waters has resulted in massive sedimentary accumulation and a significant fossil record.

Cell structure

Frustule: The diatom frustule is a highly patterned external wall composed of amorphous silica $[(\text{SiO}_2)_n(\text{H}_2\text{O})]$. Silica is often plentiful in natural waters (it is the second most abundant element in the Earth's crust) and is an energetically inexpensive source of wall material (Falkowski and Raven, 1997). The diatom frustule is constructed of two almost equal parts, termed valves, with the smaller valve (hypotheca) fitting into the larger (epitheca). Each theca is typically composed of two parts: the valve (which forms the larger outer surface) and a girdle (circular bands of silica attached to the edge of the valve). The frustule is present in all living diatoms, except following secondary loss in endosymbiotic diatoms living in some dinoflagellates (Tamura et al., 2005) and some foraminifera (Lee and Correia, 2005). Owing to their requirement for silica for cell wall biogenesis, the diatoms play a key role in the biogeochemical cycling of silica (Tréguer et al., 1995). Diatom frustule walls predominate in the sediments of the ocean floor, thus making the diatoms serious players in ocean biogeochemistry over geologically significant timescales (Kemp et al., 2000). Analysis of diatom frustule containing sediments can provide information on past environmental conditions (e.g., Reavie et al., 1998). Fossil diatom frustule deposits are even mined as diatomaceous earth and commercially used as filter material, mild abrasives, and absorbent or insulation materials (Lee, 2008). The precise method of frustule formation is still not fully understood but most models propose the formation of a matrix of organic fibrils and microtubules onto which the silica is deposited. More recently, Sumper and Kröger (2004) have suggested that silica formation takes place in intracellular compartments termed silica deposition vesicles (SDVs).

Two major categories of frustule shapes can be distinguished, that is, discoid or cylindrical cells with radial symmetry in valve view (centric diatoms) and elongated cells with a more or less bilateral symmetry (pennate diatoms). Some pennate diatoms have slits in their frustule that extends between both cell ends, the raphe system. Such diatoms are known as raphid diatoms and they possess the ability to accomplish rapid gliding motility. Other pennate diatoms lacking raphes are nonmotile and termed araphid diatoms (Round et al., 1990; Graham et al., 2009). The motive force for motility may come from

raphe-associated microtubules and attached motor proteins which drag polysaccharide rods that are liberated from the cell by exocytosis at the raphe fissure (Schmidt, 1997). Mucilage that is secreted from the raphe of some pennate diatoms may also form a stalk used for stable attachment of the cell to substrates.

Cell division and sexual reproduction: The regular asexual method of reproduction is by cell division. The valves of the parent cell become the epithecas of the daughter cells with each daughter cell producing a new hypotheca (see Lee, 2008). As a result of cell division, one of the daughter cells is of the same size as the parent cell, and the other is smaller. Once a certain minimal size (about one-third of the maximum size) is reached after several generations, this triggers the start of sexual reproduction whereby gametes are formed. As a result of the fusion of two gametes, a large diploid auxospore (zygote) is formed reestablishing the maximum size of the diatom cell. Vegetative cells of diatoms are diploid, and gamete production involves meiosis. Centric diatoms are oogamous, producing one or two egg cells per parental cell and form 4–128 sperm per parent cell as the result of mitotic divisions following mitosis (Graham et al., 2009). Centric diatom sperms are flagellates, but there is only a single flagellum (insel flagellum, see entry *Algae (Eukaryotic)*). Pennate diatoms are usually isogamous, that is, both gametes are similar in size and neither is flagellate. In addition, also the asexual formation of resting spores may act as a second mechanism of size restoration (Lee, 2008).

Plastids and storage products: Plastids are double membrane-bounded organelles usually containing the photosynthetic apparatus or some part of it. The diatom plastids are bounded by four membranes and a chloroplast endoplasmatic reticulum (see entry *Algae (Eukaryotic)*) is present. These are typical features of the plastids of most members of photosynthetic Stramenopiles which are thought to be derived from a single red algal secondary endosymbiosis (McFadden, 2001; Keeling, 2004; Palmer, 2003). The thylakoid membranes within the plastid have the typical structure of the photosynthetic Stramenopiles (heterokont algae), grouped into lamellae of three, all enclosed by a girdle lamella. Centric diatoms generally have large numbers of small discoid plastids, whereas pennate diatoms tend to have fewer plastids, sometimes only one. Due to the presence of the brown carotenoid fucoxanthin which is present in most photosynthetic Stramenopiles (see entry *Algae (Eukaryotic)*) the diatom plastids appear brown. Other characteristic accessory pigments are the chlorophylls c_1 and c_2 . Fucoxanthin and chlorophylls are bound within the light-harvesting antenna complexes by Fucoxanthin- and chlorophyll a/c -binding proteins (FCP). The FCP proteins are integral membrane proteins localized on the thylakoid membranes within the plastid, and their primary function is to target light energy to chlorophyll a within the photosynthetic reaction centers. Diatoms have chrysolaminarin as a carbohydrate storage product which

is dissolved within vacuoles in the cytoplasm, another feature shared with many photosynthetic Stramenopiles. In addition, cytoplasmatic lipid droplets occur. Diatoms are the source of unique highly branched isoprenoid alkanes and steroids which can be used as biomarkers in the water column and in sediments (see entry *Biomarkers (Molecular Fossils)*). An important survival strategy used by diatoms is to produce long-lived resting spores to buffer environmental deterioration (Round et al., 1990), although these only occur in small quantities in sediments.

Diversity and ecology

Diatoms are one of the most easily recognizable groups of major eukaryotic algae because of their unique architecturally complex siliceous cell walls. The siliceous material is laid down in certain regular patterns that leave the wall ornamented and these frustule structures are extensively used as taxonomic “fingerprints.” Diatoms are probably the most species-rich group of eukaryotic algae, with over 250 genera of extant diatoms and perhaps as many as 100,000 species occurring in both aquatic and terrestrial habitats (Norton et al., 1996; Sims et al., 2006). Many more diatom species still remain to be described and diatom species may actually number in the millions (Norton et al., 1996). Diatoms comprise the main component of the open-water marine flora and a significant part of the freshwater algal flora. While pennate diatoms are represented in about equal numbers in the freshwater and marine habitats, the centric diatoms are present predominantly in the marine environment (Lee, 2008). Diatoms are probably the most important group of eukaryotic phytoplankton. Their buoyant cells, often augmented by chitin threads or colonial adaptations, enable them to keep within the photic zone better than many other algae. Moreover, some species are able to withstand deep mixing and low light levels (Kilham et al., 1986). Water depth, photon penetration, vertical mixing, and micro-substrate conditions determine the relative importance of each habitat. Diatom productivity follows a seasonal pattern in most lakes, controlled by the variability of climate, nutrient supply, mixing regimes, and in northern latitudes the period of ice cover. Besides planktonic diatoms there are many benthic forms, growing on sediments or attached to rocks or macroalgae, and some species can also be found in soil (Lee, 2008). In freshwaters, the diatoms make up a large part of the periphyton (i.e., organisms attached to submerged vegetation or inorganic substrates), where they are attached to the substrate (e.g., forming biofilms together with cyanobacteria on tufa stromatolites in hardwater creeks, Arp et al., 2010; see Figure 1). Despite an increase in current retards the attachment of diatoms to the substrate, it causes faster growth leading to a higher standing crop in fast-flowing streams than those in slow-flowing streams (Lee, 2008).

Many diatoms exhibit growth habits and forms that trap sediments, and/or promote precipitation of carbonate

Diatoms, Figure 1 Raphid pennate diatoms recovered from tufa stromatolite biofilms of hardwater creeks: (a) diatom assemblage (biofilm sample, e.g., *Navicula* sp., *Gomphonema* sp., *Cymbella* sp.); (b) *Gomphonema* sp., (biofilm sample) with mucilaginous stalk; (c) *Gyrosigma* sp., (biofilms sample); (d) *Planothidium frequentissimum* (pure culture); (e) SEM of *Achnanthes saprophila* (pure culture; photograph taken by R. forming modern stromatolites (see entries “*Microbialites, Stromatolites, and Thombolites*,” “*Microbialites, Modern*”). Numerous authors have noted the presence of diatoms in living stromatolites in both marine environment (e.g., Golubic, 1976) and limnic and fluvial settings (e.g., Gomes, 1985). Several diatoms are conspicuous in building stromatolites, for example, *Mastogloia* sp., *Nitzschia* sp., *Amphora* sp., *Diploneis* sp., and function in a manner analogous to that of cyanobacteria in that they produce extracellular gel, are motile, phototropic, can trap and bind sediment, and produce surface irregularities of the mat (Awramik and Vanyo, 1986; Freytet and Verrecchia, 1998). Diatom mats are important sediment stabilizers in nonmarine environments (Winsborough, 1987) and in subtidal marine settings they appear to be capable of trapping and binding coarser sediment than do those dominated purely by cyanobacteria (Neumann et al., 1970). The presence of biofilms containing large amounts of solid CaCO_3 is often observed on structures submerged in hard freshwaters. The formation of such calcified biofilms may also involve trapping of calcium salts produced within the main body of water by the mucilage of diatom-rich films, and the mediation of CaCO_3 precipitation by biofilm algae, for example, via photosynthesis (Heath et al., 1995).

In warm oligotrophic seas, symbioses between nitrogen-fixing cyanobacteria and diatoms often play a significant role. *Richelia*, a heterocystous cyanobacterium, and the non-heterocystous *Trichodesmium* are believed to be the major N_2 fixers in tropical and subtropical oceans (Carpenter and Romans, 1991; Capone et al., 1997; Janson et al., 1999). In the diatom genera *Hemiaulus*, *Rhizosolenia*, and *Bacteriastrum*, *Richelia* lives as an endosymbiont between the cell wall and the frustule (Fogg, 1982; Villareal, 1994; Janson et al., 1995), with the cyanobacterial partner presumably supplying the eukaryotic partner with nitrogen and/or carbon (Rai et al., 2000). For an extensive bloom of the diatom *Hemiaulus hauckii* harboring *Richelia*, it was estimated that the N supply by N_2 fixation by the symbiosis exceeded that of nitrate flux from below the euphotic zone. High abundances of *Rhizosolenia-Richelia* and *Richelia-Chaetoceros* symbioses have been reported for the subtropical Pacific Ocean (Mague et al., 1974; Gómez et al., 2005); also free trichomes of *Richelia* have been observed there.

Evolutionary history, fossil record, and classification

Fossil diatoms are known from deposits extending from recent times back to about 180 million years ago (Kooistra et al., 2007). Molecular clock evidence suggests that diatoms appeared no earlier than 240 million years ago (Kooistra and Medlin, 1996). The oldest fossil diatoms frustules are from the Jurassic, and well-preserved, diverse floras are available from the Lower Cretaceous (Sims et al., 2006). The fossil evidence suggests that the first

diatoms lived in marine waters and had valves that were radially symmetrical. The main invasion of freshwaters appears to have been delayed until the Cenozoic. Pennate diatoms appear in the late Cretaceous and raphid diatoms in the Paleocene (Sims et al., 2006). Centric diatoms are oogamous and with numerous discoid plastids, pennate diatoms are isogamous with fewer plate-like plastids. These characters previously have led to treat the centric and pennate diatoms as two separate classes. Later, the raphid and araphid pennate diatoms were given equal taxonomic ranking so that three classes were recognized for the diatoms, Coscinodiscophyceae (centric diatoms), Fragilariophyceae (araphid pennate diatoms), and Bacillariophyceae (raphid pennate diatoms) (Round et al., 1990). In molecular phylogenies, however, it became evident that the centric diatoms are not monophyletic, but may represent two lineages to which class rank was given, Mediophyceae and Coscinodiscophyceae (Medlin and Kaczmarska, 2004; Sims et al., 2006). In turn, the molecular phylogenies show the raphid and araphid diatoms to form a monophyletic lineage, which has been recognized as the class Bacillariophyceae (Medlin and Kaczmarska, 2004; Sims et al., 2006).

Summary

Diatoms (Chromalveolates supergroup, photosynthetic Stramenopiles, Bacillariophyta) are unicellular or colonial eukaryotic algae with unique cell walls, termed frustule, composed of amorphous silica with regular patterns of ornamentation and consisting of two parts. They contain brown plastids derived from red algal secondary endosymbiosis. There are two major types: centric and pennate diatoms. Centric diatoms have a radial symmetry in valve view, containing several small plastids and are oogamous, that is, their gametes are an egg and motile spermatozooids with one flagellum. Centric diatoms have the oldest fossil record and make up two classes, Coscinodiscophyceae and Mediophyceae. Pennate diatoms have elongated cell walls with bilateral symmetry. Those pennate diatoms with a raphe exhibit gliding motility. They contain one or few plastids and are isogamous, that is, their gametes are of equal shape and without flagella. Raphid and araphid diatoms make up the class Bacillariophyceae. Diatoms are probably the most species-rich group of eukaryotic algae. They may be the most important group of eukaryotic phytoplankton in marine and freshwater environments, but are also abundant as benthic forms, growing on sediments or attached to submersed substrates, and can also be found in soils. They form important symbioses with nitrogen-fixing cyanobacteria in tropical seas. Diatom frustules predominate in the sediments of the ocean floor and the analysis of diatom frustule containing sediments can provide information on past environmental conditions. Diatoms produced significant fossil records and their fossil deposits are even mined and commercially

used. Based on fossil evidence, diatoms may be up to 240 million years old.

DINOFLAGELLATES

Dinoflagellates are a highly diverse group of flagellated protists consisting of both photosynthetic and non-photosynthetic (heterotrophic) taxa in equal proportions (Taylor et al., 2008). Dinoflagellates are an important component of the modern plankton and have been common to abundant in marine and freshwater environments since the Mesozoic. More than 2,000 extant and 2,500 fossil species have been described. Being mostly biflagellated, swimming unicells of typically 10–100 μm in diameter, they can position themselves in the water column and take full advantage of the available light and nutrients. Many genera are indicative of (paleo-) environmental conditions such as water salinity, nutrient levels, and oceanic temperature zones. In modern and ancient sediments, dinoflagellate-derived organic matter contributions can be specified by distinctive steroid biomarkers (dinosterane and related compounds, see entry “*Biomarkers (Molecular Fossils)*”). Some dinoflagellates, called zooxanthellae, are capable of forming symbioses with a phylogenetically wide range of marine protists and invertebrate animals. For further information, see entries “*Algae (Eukaryotic)*” and “*Protozoa (Heterotroph, Eukaryotic)*.”

DIVALENT EARTH ALKALINE CATIONS IN SEAWATER

Anton Eisenhauer
IFM-GEOMAR, Christian Albrechts Universität zu Kiel,
Kiel, Germany

Synonyms

Divalent cations in seawater

Definition

The most abundant divalent earth alkaline cations in seawater are Mg^{2+} , Ca^{2+} , and Sr^{2+} are simply termed the “divalent cations.” These ions and their dynamic change play a major role for the modern oceans. On long geological time scales dynamic changes of divalent cation concentrations in the oceans influenced the evolution of life and the climate evolution in the past.

Divalent cations in modern ocean water

Magnesium

Magnesium is a chemical element with the symbol *Mg*, the atomic number 12, and an atomic mass of 24.31.

Magnesium is the ninth most abundant element in the universe by mass. It constitutes about 2% of the Earth’s crust by mass, and it is the third most abundant element dissolved in seawater and it is the most abundant divalent cation followed by Ca and Sr in seawater (Brown et al., 1992). Mg ions are essential to all living cells, and is the 11th most abundant element by mass in the human body. In seawater ($S = 35$ psu), Mg is present at approximately 53 mM (mM = millimolar) (Brown et al., 1992). Only the monovalent sodium (Na^+ , 469 mM) is present at higher concentration. Magnesium is about five times more abundant than the third most abundant cation Ca (10 mM). Magnesium concentration is significantly lighter than calcium, so when compared on a weight basis, it is only about 3 times as concentrated (1285 vs. 420 ppm). Magnesium is present in seawater as a free divalent cation with water and other molecules attached to it (Brown et al., 1992; Kastner, 1999). It is estimated that each Mg^{2+} ion has approximately eight water molecules (ligands) tightly bound to it. A small portion (about 10%) of the magnesium is present as a soluble ion pair with sulfate (MgSO_4), and much smaller portions are paired with bicarbonate (MgHCO_3^+), carbonate (MgCO_3), fluoride (MgF^+), borate ($\text{MgB}(\text{OH})_4^+$), and hydroxide (MgOH^+).

While these ion pairs comprise only a small portion of the total magnesium concentration, they influence seawater chemistry to a large extent. In the case of carbonate (CO_3^{2-}), for example, the ion pairing to magnesium stabilizes the carbonate that it is present in far higher concentrations than it would be present in the absence of magnesium. This effect makes seawater a much better buffer in the pH range of 8.0 than it otherwise would be. Without this ion pairing, seawater pH might be significantly higher, and more susceptible to dynamic changes. The average residence time for a magnesium ion in seawater is on the order of several tens of millions of years. That time is substantially longer than that for Ca (~one million years) and aluminum (Al, 100 years), but less than Na (~250 million years). The long seawater residence time of Mg in seawater is a measure of its fairly unreactive chemical behavior indicating that it does get taken out of solution through various biological and chemical processes.

Sources and sinks for magnesium in the oceans

In the present-day ocean, the two most important calciumcarbonate (CaCO_3) polymorphs – low Mg-calcite and aragonite – are the most prevalent carbonates and major sinks for Mg replacing Ca to some extent in the crystal lattice. Mg also precipitates together with Ca directly from the water in some evaporitic settings, as well as by the dissolution and reprecipitation of calcite with magnesium replacing calcium in the crystal structure. Dolomite, a high magnesium type of calciumcarbonate usually does not form in the well-oxygenated modern oceans, although bacterial alteration of seawater is reported to induce dolomite precipitation (Kastner, 1999; McKenzie, 1981) in certain marine anoxic environments.

The amount of magnesium estimated to exist as dolomite deposits suggests the importance of dolomitization as a magnesium sink in the past, despite its low prevalence today (Wilkinson and Algeo, 1989). In general, the geological Mg record shows a general trend of increasing abundance of dolomite in sediments of increasing age (Wilkinson and Algeo, 1989). The relative lack of dolomite formation today might indicate differences in past seawater chemistry, climatic and environmental conditions that are more conducive to dolomite formation.

The interaction of hydrothermal waters with basalt at the mid-ocean ridge (MOR) effectively removes magnesium from the water to the basalt, and in exchange, calcium becomes enriched in the water (Mottl and Wheat, 1993). Estimates for the molar exchange rate of Mg to Ca at the MOR are close to unity. These models also predict that interaction at the MOR is a sufficient sink to explain the balance of magnesium in the ocean, as well as being a significant source for calcium.

Marine geological investigations at the mid-ocean ridge estimate a flux rate of the entire ocean volume through the accretion zone every 8 million years, or about 1.75×10^{17} g/year, a fraction of the flux rate for rivers of about 4.6×10^{19} g/year (Mottl and Holland, 1978). It has also been demonstrated through pore water profiles that magnesium and calcium chemically interact with the underlying crystalline basement resulting in a decrease of magnesium concentration and an increase in calcium concentration with depth below seafloor in the sediment column (Holland, 1984).

Calcium

Calcium (Ca) is the chemical element with the symbol *Ca* and atomic number 20. It has an atomic mass of 40.078. Calcium is a soft grey alkaline earth metal, and is the fifth most abundant element by mass in the Earth's crust. Calcium is also the fifth most abundant dissolved ion in seawater by both molarity and mass, after sodium, chloride, magnesium, and sulfate. Ca is essential for living organisms, particularly in cell physiology, where movement of the calcium ion Ca^{2+} into and out of the cytoplasm functions as a signal for many cellular processes. As a major material used in mineralization of bones and shells, calcium is the most abundant metal by mass in many animals.

Sources and sinks for calcium in seawater

Calcium is the second most abundant divalent cation of the major ions in seawater with a concentration of about 410 ppm (Brown et al., 1992). Ca variations in the oceans are often caused by changes in salinity, where the calcium goes up and down just as the salinity and the dynamic changes of the input of rivers, which are often greatly enriched in calcium relative to other ions such as sodium. Calcium is also frequently enriched in hydrothermal vent water released from the ocean bottom. The calcium is

dissolved from the hot basalt as the water passes through it, and is released to the ocean. Compared to other conservative cations Ca has a relative short mean residence time of about one million year or less which may reflect its important role in marine biomineralization and other chemical processes. One interesting aspect of calcium in seawater is that the calcium concentration can be higher in deep ocean water than in surface water due to the dissolution of CaCO_3 and the recycling of Ca in the deep ocean. Ca can also locally be depleted in places where precipitation of calcium carbonate is especially rapid. This includes the Bahamas Banks (where oolitic aragonite is precipitated), in parts of the Red Sea, and presumably in some lagoons where calcification is high and the water volume is small.

Chemical state of calcium in seawater

In fresh water below pH 11, Ca ions are essentially free. They are bound only to oriented water molecules and move about independently of all other ions in the solution. However, complexation may also occur with other chemical components such as dissolved phosphate, nitrate, or carbonate. This so-called hydration sphere is quite strongly attached to the ion in water, with about eight water molecules tightly attached in the first hydration shell. Beyond this first hydration shell other water molecules are arranged in a second shell in a looser way. All water molecules around the ion are very rapidly exchanging, but those closest to the ion exchange more slowly and move with it as it moves through the solution.

In seawater, the majority of calcium ions are still free. However, some (~10–15%) are present as an ion pair with sulfate, forming the neutral soluble ion pair CaSO_4 . Calcium similarly forms ion pairs with carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-). While these comprise a small fraction of the total calcium, the calcium carbonate ion pair comprises a fairly large portion of the total carbonate (together with Mg, about two third of the carbonate). These ion pairs consequently tend to lower the free concentration of carbonate, and thereby inhibit precipitation of CaCO_3 and increasing its solubility. In seawater, Ca also forms ion pairs with fluoride, hydroxide, borate, various forms of phosphate, and other less abundant ions. In almost all cases the effect of calcium is smaller than the effect of magnesium on these ions, both because the concentration of magnesium is higher.

Calcium carbonate in seawater

A very important aspect of Ca is its supersaturation in seawater. Supersaturation means that given the right circumstances, it will precipitate as solid calcium carbonate. Supersaturation can be described as:

$$K = [\text{Ca}^{++}][\text{CO}_3^{-}] \quad (1)$$

When $K = K_{sp}^*$ (the solubility product constant in seawater at any given temperature, pressure, and salinity), the solution is saturated. When K exceeds the K_{sp}^* , the solution is supersaturated and when the product of the concentration of calcium and carbonate is less than K_{sp}^* , the solution is undersaturated, and calcium carbonate can dissolve. In normal seawater, the product of calcium and carbonate is about 3 times the K_{sp}^* of aragonite and 5 times that of calcite.

The supersaturation (Ω) for calcium carbonate in seawater is given by:

$$\Omega = [Ca^{++}][CO_3^{--}]/K_{sp}^* \quad (2)$$

The higher Ω is, the more likely precipitation is to take place. At $S = 35$ psu and 1 atmosphere pressure, the K_{sp}^* decreases slightly as the temperature rises. Millero (1995) provides a series of long equations for calculating K_{sp}^* for both aragonite and calcite. For aragonite, the $\log K_{sp}^*$ drops from -6.19 at 25°C , to -6.23 at 40°C to -6.44 at 80°C . In relative terms, the K_{sp}^* has gone from 1 to 0.91 to 0.55 over this temperature range. Likewise for calcite, the relative K_{sp}^* has changed from 1 to 0.96 to 0.73 over this range.

Calcium (magnesium) carbonate precipitate from seawater

One situation in which calcium carbonate can precipitate involves adding calcium carbonate seed crystals to seawater. In many cases, this action will initiate precipitation of calcium carbonate (and magnesium as well). This precipitation typically does not proceed until supersaturation is gone, but may be stopped by some other processes. Furthermore, precipitation takes place if the supersaturation is pushed to unusually high levels. This can be caused by a rise in pH, a rise in temperature, or more obviously, by a rise in either calcium or carbonate.

However, chemical interaction of various cations, mainly Mg, permit the ocean to be supersaturated. Without these processes, it is unlikely that the ocean could remain supersaturated, and might even make it impossible for corals to maintain skeletons without expending considerable effort to prevent dissolution. Magnesium holds onto carbonate ions and reduces their free concentration, thereby reducing the likelihood of precipitation onto calcium carbonate surfaces. Furthermore, Mg gets onto the growing surface of the crystal, essentially poisoning further precipitation of calcium carbonate due to the higher activation hydration energy of Mg. Note that while both of these processes inhibit precipitation of calcium carbonate, the first actually increases the solubility, whereas the second does not. It is worth noting that the solubility of calcium carbonate in seawater is about 26 times higher than in freshwater at the same temperature. Other processes that inhibit crystal growth in seawater involve both

phosphate and organic compounds that get onto the growing crystal like Mg.

Bicarbonate acidity shift with temperature

As water is heated, the equilibrium between bicarbonate and carbonate (Equation 3) is shifted toward carbonate.

$$K_a^* = [CO_3^{--}][H^+]/[HCO_3^-] \quad (4)$$

$$[CO_3^{--}] = K_a^* [HCO_3^-]/[H^+] \quad (5)$$

$$pK_a^* = -\log K_a^* \quad (6)$$

This shift toward carbonate is evidenced by the shift in the seawater pK_a^* for bicarbonate from 9.00 at 25°C to 8.68 at 40°C and 8.16 at 80°C (calculated from equations provided by (Millero, 1995); the * simply indicates that it is in seawater at a given temperature, pressure, and salinity). From Equation 5 (and related derivations) it is evident that if K_a^* rises, $[CO_3^{2-}]$ and $[H^+]$ will rise, and $[HCO_3^-]$ will decline.

Strontium

Strontium in seawater

Strontium, with a molecular weight of ~ 87.5 g/mole is significantly heavier than calcium (40.07 g/mole) or magnesium (24.3 g/mole). In physical size, a strontium ion is about 13% larger than a calcium ion, and 70% larger than a magnesium ion. In seawater ($S = 35$ psu), Sr is present at approximately 90 μM . By concentration, it is the fifth most abundant cation but is the third most abundant divalent cation. In mass units, it is present in seawater at about 8 ppm. The strontium concentration is largely constant across the oceans, with local variations of only 2–3% relative to calcium (DeVilliers and Nelson, 1999; Bernat et al., 1972). As salinity varies in lagoons and estuaries strontium rises and falls accordingly. It was generally accepted that the strontium concentration was also unchanged with depth, but more recent measurements have shown that the strontium concentration rises with depth due to the presence of *acantharians* that deposit strontium sulfate skeletons, slightly depleting the surface of Sr. As these free floating organisms die and settle to the bottom, the deeper waters become enriched in strontium as the skeletons dissolve (DeVilliers and Nelson, 1999).

Most of the strontium is present as the free ion, with only water molecules attached to it (Millero, 1995). A small portion (about 10%) of the strontium is present as a soluble ion pair with sulfate ($SrSO_4$), and much smaller portions are paired with bicarbonate ($SrHCO^+$), carbonate ($SrCO_3$), fluoride (SrF^+), borate ($SrB(OH)^{4+}$), and hydroxide ($SrOH^+$). The average residence time for a strontium ion in the ocean is on the order of

10–20 million years. That time is similar to magnesium (20–50 million years) and is substantially longer than that for calcium (~1 million year) and aluminum (100 years). It is also substantially lesser than sodium (~250 million years). All three divalent cations are chemically very similar. Size is the primary difference which may cause some chemical differences, especially the solubility of certain strontium salts. Strontium carbonate (strontianite) is less soluble than calcium carbonate, which in turn is less soluble than magnesium carbonate. Interestingly, strontium sulfate (celestite) is much less soluble than calcium sulfate and magnesium sulfate. While none of these are actually saturated in seawater, strontium sulfate is close, at 30% of saturation (McManus et al., 2000). That difference is important, and in fact some organisms use strontium sulfate as a skeleton.

Organisms that use strontium for skeletal formation

Although shells of marine mineralizing species are usually made of calcium carbonate there are few species like *Cephalopods*, *Radiolaria*, *Gastropods* which enrich Sr in their calcium carbonate skeleton. However, there is one unique species *Acantharia* which is probably the main user of strontium in the ocean forming its skeleton completely out of SrSO_4 instead of CaCO_3 (c.f. Kinsman and Holland, 1969). These free floating unicellular microorganisms are related to *radiolaria*. They have radiating spines of strontium sulfate that are largely external to the central cytoplasm. Inside the cytosol the spines are connected. *Acantharia* live in the upper regions of the oceans where they deposit their strontium sulfate skeletons. Presumably, the skeletons of all Sr using species are protected from dissolution due to organic coatings. However, when, for example, *Acantharia* individuals die and sink, the protection of the strontium sulfate is lost, exposing the strontium sulfate to the open water, resulting in dissolution. They are populous enough that they are an important part of the strontium cycle in the oceans including river and hydrothermal vent. Certain species of *radiolaria* also use strontium sulfate, despite having silica skeletons. The radiolarian *Sphaerzoum punctatum*, for example, release flagellated swimmers during reproduction which contain celestite. These crystals are deposited inside a cytoplasmic vacuole, and have a 50–100 nm thick coating of organic material on it. Similar to *Acantharia* this coating may reduce the likelihood of dissolution of the celestite.

Reconstruction of past and present environmental information from divalent cation ratios (here Mg/Ca, Sr/Ca) and Ca isotope fractionation Mg/Ca-thermometer

The observation that magnesium was higher in marine carbonates precipitated in warmer water was confirmed for neritic foraminifer shells which are composed of high magnesium calcite (<5% MgCO_3). Another study suggested that pelagic foraminifera, which are composed

of low-magnesium calcite (<1% MgCO_3), might also follow this pattern (Savin and Douglas, 1973). Several studies also demonstrated that inorganic carbonates followed the same pattern (c.f. Katz, 1973). This latter point is important because it indicates that the temperature influence could not be entirely biological (Lea, 2003). The underlying basis for Mg/Ca paleothermometry is that the substitution of Mg in calcite is endothermic and therefore is favored at higher temperatures. The enthalpy change for the reaction based on the more recent thermodynamic is 21 kJ/mol which can be shown using the van't Hoff equation to equate an exponential increase in Mg/Ca of 3%/°C (Lea et al., 1999). Foraminifera shells differ from the thermodynamic prediction in two fundamental ways. First, foraminifera contain 5–10 times lower Mg than predicted from thermodynamic calculations (Lea, 2003). Second, the response of shell Mg to temperature is ~3 times larger than the thermodynamic prediction and inorganic observation, averaging $9 \pm 1\%/^\circ\text{C}$. Why the latter effect is so is not known, but it has several important implications for Mg/Ca paleothermometry. First, it increases the sensitivity of this approach. Second, it raises the question of why the response is so much greater in foraminifera and if the augmentation of the response depends on secondary factors that might change over geological time (Lea, 2003).

At present, several planctonic species (e.g., *G. sacculifer*, *G. bulloides*, *G. ruber* and *O. universa*) have been calibrated by culturing and fit with equations of the form:

$$\text{Mg/Ca} = (\text{mmol/mol}) = be^{mT} \quad (7)$$

Where b is the pre-exponential constant, m is the exponential constant, and T is the temperature (Lea et al., 1999). Fitting Mg/Ca-temperature data with an equation of this form has the dual advantage of allowing for an exponential response while also parametrizing, by the use of the natural logarithm. Calibration results for the three species mentioned above indicates exponential constants between 0.085 and 0.102, equivalent to 8.5%, 10.2% increase in Mg/Ca per°C (Nürnberg et al., 1996; Lea et al., 1999; Kisakürek et al., 2009).

Note that the Mg concentration of foraminifer shells, as well as other carbonates, is susceptible to change via dissolution. At present, scientists accept that dissolution alters the Mg/Ca content of foraminifera shells and instead are investigating the degree to which such changes occur and whether correction factors are possible, and the degree to which dissolution affects Mg/Ca ratios.

Results on quaternary timescale

Mg/Ca thermometry has led to a number of important findings for paleoceanographic and paleoclimatic research. These include documenting the history of subpolar Antarctic sea surface temperature (SST) variations (Mashiotto et al., 1999), tropical Atlantic and Pacific SST changes (Hastings et al., 1998; Nürnberg et al.,

2000), and changes in bottom water temperature in the Atlantic and Pacific.

Among these Mg/Ca results, the most important are those that are available for the tropics. Past SST changes in the tropics have been a contentious issue because the actual glacial–interglacial changes are relatively small ($<5^{\circ}\text{C}$) and therefore more difficult to detect. However, applying Mg/Ca-thermometry to a sediment core from the Ontong Java Plateau which lies on the equator in the center of the western Pacific warm pool and covering the last 500,000 years indicate that glacial SST cooling was systematically $\sim 3^{\circ}\text{C}$ cooler than modern conditions and that this cooling occurred during each of the last five major glacial episodes. Another important observation from Mg/Ca studies is the fact that glacial warming appears to lead ice sheet demise as seen from the oxygen isotope record ($\delta^{18}\text{O}$) by $\sim 3,000$ years (Lea et al., 2000). This observation suggests a prominent role for the tropics in pacing ice age cycles. However, local changes in salinity may also influence $\delta^{18}\text{O}$ -records resulting in apparent shifts between Mg/Ca and $\delta^{18}\text{O}$ -records.

Sr/Ca-thermometer

Early studies indicated that there was an inverse relationship between seawater temperature and strontium content of both inorganically precipitated calcium carbonate and coral aragonite of about $1\text{‰}/^{\circ}\text{C}$. Modern calibrations indicate a sensitivity of about $0.6\text{‰}/^{\circ}\text{C}$ decrease in Sr/Ca. The relationship between coral Sr/Ca and seawater temperature is given as a linear function of the form:

$$\text{Sr/Ca (mmol/mol)} = b + m(\text{SST}) \quad (8)$$

The thermodynamic prediction for strontium substitution in aragonite is actually an exponential response with an inverse temperature dependence, a consequence of the negative enthalpy (exothermic) nature of the reaction in which strontium substitutes for calcium in aragonite. The single inorganic aragonite precipitation study indicates a slope m of 0.039 and an intercept b of 10.66 mmol/mol (Kinsman and Holland, 1969). Calibrations are also available for a number of coral species, but mostly for species of *Porites* (c.f. Beck et al., 1992). Values of the intercept b , which determines the absolute Sr/Ca for a particular temperature, range from 10.3 to 11.3. Values of the slope m , determining the temperature sensitivity range from 0.036 to 0.086.

Results on historical timescale

Among other studies a few long time series of Sr/Ca have been published from Rorotonga and the Great Barrier Reef (GBR) in the South Pacific (Linsley et al., 2000). These SST records show clear interannual variability as well as distinct secular trends. For example, the GBR records which are an average of eight different coral cores, indicate a secular shift to warmer SST in the youngest part of the records (after ~ 1950). Results from the Rorotonga

site are somewhat different and suggest a prominent cooling ~ 1750 followed by a series of decadal oscillations that correlate in the twentieth century with the Pacific Decadal Oscillation (Mantua et al., 1997). The warm period recorded in the mid-eighteenth century at the Rorotonga site appears to be corroborated in the GBR sites, although with a reduced magnitude.

Ca isotope thermometry

The possibility of using calcium isotopes for paleothermometry is a very new idea that is based on the empirical observation of temperature-related fractionation between the isotopes ^{40}Ca and either ^{44}Ca or ^{42}Ca (expressed as $\delta^{44/40}\text{Ca}$ or $\delta^{44/42}\text{Ca}$). This potential paleothermometer has been calibrated in neritic benthic foraminifera (DeLaRocha and DePaolo, 2000), a spinose tropical planktonic foraminifera (Näglér et al., 2000), and a subtropical planktonic foraminifera (Gussone et al., 2003). Convincing evidence of the potential utility of this new paleothermometer comes from the study of (Näglér et al., 2000), which demonstrates an increase of 0.24‰ in shells of the planktic species *G. Sacculifer* $\delta^{44/40}\text{Ca}/^{\circ}\text{C}$. Down-core measurements from a core in the tropical Atlantic indicate that shells from glacial intervals are $\sim 0.5\text{--}1.0\text{‰}$ depleted in $\delta^{44/40}\text{Ca}$ consistent with colder glacial temperatures (Hippler et al., 2006). The $\delta^{44/40}\text{Ca}$ -temperature sensitivity is species dependent showing a much lower sensitivity for *O. universa* of only about $0.02\text{‰}/^{\circ}\text{C}$.

Summary

The divalent alkaline earth cations magnesium, calcium and strontium are key elements for the understanding of inorganic and biologically mediated mineralization and calcification. High resolution measurements of element partitioning and isotope fractionation will help to understand the processes controlling the trace element pathways from a bulk solution to the site of calcification. In particular, the recent findings of Fietzke and Eisenhauer (2006) of temperature dependent Sr isotope fractionation may further help to decipher biocalcification processes.

Bacterial dolomite; Organogenic dolomite

Definition

Dolomite. Widely distributed rock-forming mineral, $\text{CaMg}(\text{CO}_3)_2$. Usually, white or colorless, but can be yellowish and brown with rhombohedral crystals exhibiting curved, composite faces. It also occurs with massive and granular habit and has rhombohedral {1011} cleavage.
Dolomitization. The process of converting calcite in limestones to dolomite by the action of magnesium-bearing solutions.

Introduction

The mineral dolomite is notoriously difficult to synthesize under laboratory conditions at low temperature (less than 50°C) and despite its abundance in the ancient rock record, scarcely forms in modern environments. This apparent departure from the geologists' guiding principle that the "present is the key to the past," established by Hutton's principle of uniformitarianism, is at the heart of the "Dolomite Problem," which is a twofold issue (e.g., McKenzie, 1991).

The dolomite problem

The first aspect of the problem is the abundance of massive dolomites, comprised of secondary or replacement dolomite, in ancient rock, but their striking absence in modern environments. Secondary dolomite is formed through the process of dolomitization, in which the mineral calcite is replaced by dolomite through interaction with Mg-rich fluids (Pursar et al., 1994; Burns et al., 2000, and references therein). The second aspect of the dolomite problem is the difficulty associated with the synthesis of primary dolomite (precipitation of the mineral directly from aqueous solution) at low temperature. Despite conditions favoring its formation and ample time for precipitation, researchers have been unsuccessful in synthesizing dolomite abiotically under laboratory conditions (e.g., Land, 1998), and attribute this lack of success to slow reaction kinetics (Hardie, 1987; Sibley et al., 1987). Recent research has confirmed long-held assertions (e.g., Nadson, 1928; Neher, 1959) that microorganisms play a fundamental role in the formation of dolomite at low-temperature.

Microorganisms as catalysts for dolomite formation

Vasconcelos et al. (1995) successfully synthesized ferroan dolomite in the presence of a native microbial consortium collected from a modern dolomite-precipitating environment, ushering in extensive scrutiny of microorganisms and microbial processes that facilitate dolomite formation. Modern dolomite-forming environments are isolated, and in those that have been extensively studied, dolomite formation is intimately linked to microbial populations and associated activity, for example, the Coorong region of Australia in coastal lakes (Wright, 1999; Wright and Wacey, 2005), Lagoa Vermelha, Brazil, a hypersaline coastal lagoon (Vasconcelos and McKenzie, 1997), and the Persian Gulf sabkhas, evaporitic salt pans (Barbieri et al., 2006). Evidence of primary dolomite precipitation from shallow and deep sea marine sediments, soils, and groundwater has been documented (e.g., Hardie, 1987; Lumsden, 1988; Whipkey et al., 2002; Roberts et al., 2004), but the volume of dolomite in these settings is typically minor, forming as thin beds or nodules. All of these environments and their native microbial communities provide an insight into the populations and the mechanisms by which microorganisms mediate dolomite formation.

Microorganisms implicated in dolomite formation

Whereas a wide variety of microorganisms has been implicated in dolomite formation, the best documented metabolic guild is those bacteria carrying out dissimilatory sulfate reduction under anaerobic conditions. These bacteria utilize organic carbon coupled to sulfate as a terminal electron acceptor for energy, thereby removing sulfate and generating alkalinity. Researchers have inferred their presence from geochemical indicators (e.g., Vasconcelos and McKenzie, 1997), culturing experiments (Warthmann et al., 2000; Wright and Wacey, 2005), and non-culture-based identification. Some of the organisms identified include *Desulfostipes sapovorans* and *Desulfosarcina* spp. (Wright and Wacey, 2005) and *Desulfovibrio brasiliensis* (Warthmann et al., 2000).

Two other types of bacterial metabolic pathways have also been shown to mediate low-temperature dolomite formation. Two moderately halophilic aerobic heterotrophs, *Halomonas meridiana* and *Virgibacillus marismortui*, produce dolomite under laboratory conditions (Sánchez-Román et al., 2008). These organisms utilize nitrogenated organic matter coupled to oxygen as a terminal electron acceptor, consuming acidity and producing alkalinity. The other bacterial metabolic guild implicated in dolomite precipitation is the sulfide oxidizers, which oxidize H₂S, producing sulfate and acidity (Moreira et al., 2004). This interaction has been inferred from geochemical and isotopic data from Lagoa Araruama, Lagoa Vermelha, and Brejo do Espinho, Brazil, and the production of H₂S in these environments is produced via bacterial sulfate reduction, also thought to produce microbial dolomites.

Additional metabolic pathways linked to dolomite precipitation are part of the Archaeal domain, and involve either the production or utilization of methane. Anaerobic methane oxidizers, which utilize methane and generate alkalinity, in concert with methanogens, were found to control low temperature dolomite formation in deep-sea sediments as inferred from geochemical and isotopic data (Moore et al., 2004). Isotopic signatures from a range of ancient sediments indicate that the activity of methanogens is linked to dolomite formation (e.g., Mazullo, 2000). Additionally, recent studies have linked methanogenesis to the precipitation of dolomite in shallow groundwater (Roberts et al., 2004). Laboratory experiments identified two methanogenic metabolic pathways associated with dolomite formation, acetoclastic and autotrophic. Acetoclastic methanogens cleave acetate forming methane and carbon dioxide, whereas autotrophic methanogens combine carbon dioxide and hydrogen to form methane. These pathways were associated with *Methanosaeta* spp. and *Methanobacterium* spp., respectively (Kenward et al., 2009).

Mechanisms for microbial mediation of dolomite

Although it is clear that the presence of microorganisms under some geochemical conditions promotes dolomite

precipitation, there is still debate as to *how* microorganisms are involved in facilitating precipitation.

The most important criterion for the precipitation of dolomite is that supersaturated conditions exist. Many of the microbial guilds discussed previously are capable of driving supersaturation of dolomite as a result of their metabolic pathways. Sulfate reduction, aerobic heterotrophic respiration, anaerobic methane oxidation, and acetoclastic methanogenesis produce alkalinity as a by-product of metabolism, which increases supersaturation with respect to carbonate minerals. Sulfide oxidation produces acidity, which lowers the saturation state of competing carbonate minerals, thus, favoring the supersaturation of dolomite. Sulfate reduction, aerobic respiration of nitrogenated carbon compounds, autotrophic methanogenesis, and anaerobic methane oxidation increase pH in the system, which also favors supersaturation of the carbonate minerals (Madigan and Martinko, 2005).

Although microbial metabolism can generate solutions supersaturated with respect to dolomite, it has been demonstrated that supersaturation alone does not lead to the precipitation of dolomite and, therefore, microbes likely facilitate dolomite formation by removing additional kinetic barriers present at low temperatures. For example, the sulfate inhibition model asserts that sulfate is a kinetic inhibitor of dolomite precipitation because of the strong neutral complex it forms with magnesium (MgSO_4^0), essentially decreasing the Mg available to form dolomite (Baker and Kastner, 1981). This was demonstrated at low sulfate concentrations, hence, favoring those microbial interactions which either remove sulfate or occur under these conditions (i.e., sulfate reduction, methanogenesis, and anaerobic methane oxidation). Other researchers have disputed this model due to the fact that many modern dolomites are formed under conditions with sulfate concentrations equal to or above that of seawater (Hardie, 1987) suggesting that sulfate inhibition is not the sole kinetic barrier to dolomite formation. Laboratory studies have shown that at very low or very high sulfate concentrations,

dolomite formation is promoted (Brady et al., 1996; Siegel, 1961). Recently, Sánchez-Román et al. (2009) demonstrated that two moderately halophilic aerobic heterotrophic bacteria could promote dolomite precipitation at sulfate concentrations ranging from 0 to 56 mM. Taken together, these data suggest that sulfate may indeed be an inhibitor to dolomite formation under certain conditions, but is likely not the sole kinetic barrier to precipitation.

One common observation in modern microbial dolomites is the intimate association between the precipitated dolomite and the cell wall of the microorganism or extracellular polymeric substances (EPS) produced by the microorganisms. These observations, in combination with evidence of cell-associated mineral nucleation (e.g., Schultze-Lam et al., 1996; Fortin et al., 1997; Douglas and Beveridge, 1998), have lead to the hypothesis that these biological surfaces are involved in the nucleation of dolomite. Laboratory experiments analyzing the charge character of the cell wall or structure, have implicated nucleation directly onto the cell wall (Figure 1; van Lith et al., 2003a; Roberts et al., 2004; Kenward et al., 2009; Bosak and Newman, 2003). Other laboratory investigations mimicking EPS-like conditions or utilizing EPS directly, have shown that nucleation occurs on these substances (Figure 1; Sánchez-Román et al., 2008; Bontognali et al., 2008). Nucleation onto EPS, rather than the cell wall, may benefit the cell by avoiding entombment and is consistent with the fact that cellular material is rarely observed in microbial carbonates (Bontognali et al., 2008).

There are a wide range of potential mechanisms by which the microbial cell wall or EPS may influence mineral precipitation mechanisms and kinetics, including heterogeneous nucleation on the cell wall; enhanced rates of growth via the catalytic influence of organic molecules or surface functional groups; substrate-based coprecipitation; and oriented (epitaxial) aggregation growth (e.g., Fowle and Fein, 2001; Banfield et al., 2000; Chan et al., 2004; Rancourt et al., 2005;

Dolomite, Microbial, Figure 1 Scanning electron photomicrographs of dolomite formed in freshwater in the presence of methanogenic microorganisms. **Panel a** shows a cell embedded in EPS and encrusted with dolomite. Arrow indicates one well-formed crystal. **Panel b** shows a more developed platy crystal of dolomite. Oval denotes boundary between EPS and crystal edge. Note nanoglobules in EPS. Images courtesy of Paul A. Kenward with special thanks to the University of Kansas MAI.

Elhadj et al., 2006; see also Chapters *Microbialites, Modern and Extracellular Polymeric Substances (EPS)*). In particular, Elhadj et al. (2006) demonstrated that small organic molecules, such as those found in cellular material and EPS, influenced calcite growth rates via both electrostatic interactions and their ability to facilitate the release of water molecules around the calcium cation during precipitation. Desolvation of cations has been considered the rate limiting step in many precipitation reactions (Nielsen, 1984) and is consistent with the findings of Brady et al. (1996), who found that dehydration and carbonation of Mg^{2+} was the probable rate-limiting step for dolomite formation at room temperature.

Microbial signatures preserved in dolomite

Two primary signatures preserved in ancient rock are commonly used to classify dolomites as microbial in origin: morphology and textures of the rocks and carbon isotopic values. It has been recognized for some time that biogenic processes impact carbonate mineral morphology and, since the identification of aragonite needle dumbbells as biogenic features (Chafetz and Folk, 1984), these features and others have been considered proxies for bacterially mediated carbonate precipitation. Laboratory studies of microbial dolomite have produced dumbbells (Warthmann et al., 2000; van Lith et al., 2003b), spheroids (Sánchez-Román et al., 2008), nanoscale globules (Figure 1b; Sánchez-Román et al., 2008; Bontognali et al., 2008; Vasconcelos et al., 1995), nanoscale rhombs attached to cells (Figure 1a; Roberts et al., 2004), and platy crystal aggregates (Figure 1b; Kenward et al., 2009). Although many of these features are observed in ancient rocks, they are not limited to a biogenic origin and, therefore, not definitive evidence of microbial precipitation.

The composition and isotopic signature associated with carbonate precipitates has been linked with specific microbial communities, including iron reduction, sulfate reduction, and methanogenesis (e.g., Curtis et al., 1986). Those dolomites associated with sulfate reduction are typically low in Fe (due to pyrite precipitation) and ^{13}C -depleted, whereas methanogenic dolomites tend to have higher Fe abundance and are ^{13}C -enriched. Potentially, diagnostic $\delta^{18}O_{\text{dolomite}}$ signatures related to temperature (or potentially depth) of precipitation have been difficult to interpret due to the lack of experimental data for low temperature dolomite. Vasconcelos et al. (2005), however, proposed a paleothermometer for dolomite precipitation based on dolomite produced by sulfate reducing bacteria. Despite these efforts, extraordinary fractionation of $\delta^{18}O_{\text{dolomite}}$ has been observed via methanogenic activity that is inconsistent with the current paleothermometer (e.g., Roberts et al., 2004).

Summary

For more than a century, the Dolomite Problem has stumped scientists. In recent years, progress towards

a solution has been made by understanding the role of microorganisms in precipitating the mineral dolomite in low temperature (less than 50°C) environments. Many microorganisms, in both the Archaeal and Bacterial domains, are involved in these reactions, suggesting that microbial dolomite can form in a variety of biogeochemical environments. Changes in environmental conditions favoring one microorganism over another throughout time, is a potential explanation for the observed changes in abundance of dolomite from the past to the present. The mechanism by which microorganisms actually facilitate precipitation and increase reaction progress, is still debated. However, recent data point to a mechanism involving the microbial cell wall or cellular exudates overcoming kinetic barriers rather than a metabolic or geochemical control.

EARLY PRECAMBRIAN EUKARYOTES

Joachim Reitner
University of Göttingen, Göttingen, Germany

Definition

Eukaryotes are probably the result of endosymbiosis, and basically three types exist. The basic ones are the simplest eukaryotic cells with a nucleus only (*Giardia*) (Graczk, 2005). Secondly, protists have mitochondria, which have been proposed to have an alpha-proteobacterial origin (Sagan (Margulis), 1967). Finally, beside mitochondria, cells of eukaryotic algae contain chloroplasts, former single-celled cyanobacteria achieved via endosymbiosis (Mereschkowsky, 1905; Wallin, 1920; Sagan (Margulis), 1967). The geological record of protists begins long before the Ediacaran vendobionts. Possibly stem group protists were found in ca. 3 Ga-old rocks (Javaux et al., 2010). Within the Late Mesoproterozoic rocks, the divergence of major eukaryotic clades is observed. Beside the fossil record of early eukaryotes, related biomarkers (steranes) were found in up to 2.7 Ga-old rocks, which may support the early origin of eukaryotes before the Great Oxidation Event (Brocks et al., 1999; Brocks et al., 2003a, b). However, the syngeneity of the biomarkers used for the interpretation has recently been questioned (Rasmussen et al., 2008) and the first appearance of eukaryotic biomarkers is still disputed (Brocks

et al., 1999; George et al., 2008; Rasmussen et al., 2008; Waldbauer et al., 2009).

The oldest known single-celled eukaryotes are acritarchs, probably ancestors of dinoflagellates. Acritarchs played a significant role in Proterozoic oceans, and the first record comes from the 3.2 Ga-old Moodies Group of South Africa (Javaux et al., 2010). This finding is surprising, since eukaryotic metabolisms normally need oxygen, and the Great Oxidation Event took place about 700 My later, between 2.32 and 2.45 Ga. A similar discrepancy emerged from the first appearance of eukaryotic biomarkers in 2.7 Ga-old rocks (Brocks et al., 1999). Although often controversially debated, biomarker records may give excellent indications to the diversification of major phylogenetic clades. For instance, the distribution of 24-isopropylcholestane revealed a high abundance of (demo-)sponges in the Cryogenian (McCaffrey et al., 1994; Love et al., 2009), thus suggesting sufficient oxygen in shelf regions already 100 My prior to the Cambrian explosion. Furthermore, early Precambrian eukaryotic life is not only indicated by biomarker findings. In some diagenetically early silicified stromatolites, well-preserved eukaryotic cells have been described. The best material is known from the 1.88 Gy-old Gunflint Chert (Ontario, Canada) (Fralick et al., 2002; Awramik and Barghoorn, 1977). *Eosphaera tyleri* from these cherts is probably an eukaryotic cell (Kazmierczak, 1979). Beside the single-celled eukaryotes, few larger fossils which are most likely multicellular organisms are known, such as *Grypania spiralis* from the Mesoproterozoic Gaoyuzhuang Formation (China) and disk-shaped centimeter-sized organisms like *Chuaria* (Knoll et al., 2006).

In the Cryogenian and Ediacaran, the diversity of eukaryotes, including fungi and lichens, increased significantly. It is obvious that the increase of diversity and size

is related with the Snowball Earth scenarios and increase of oxygen in the atmosphere.

EDIACARAN BIOTA

Dmitriy Grazhdankin
 Russian Academy of Sciences, Novosibirsk, Russia

Definition

Ediacaran period: An interval in the history of earth after the Marinoan/Varanger glaciation of the Neoproterozoic Era (see Chapter *Snowball Earth*), but before the Cambrian radiations. This interval marks the introduction of complex macroscopic organisms, leading to a revolution in the structure and evolution of marine paleocommunities, including the establishment of multi-level trophic structures, coevolutionary predator–prey interactions and infauunal activity.

Ediacaran biota: A highly distinctive assemblage of Ediacaran-age macroscopic organisms preserved as casts and moulds in siliciclastic, volcanoclastic, and carbonate sediments.

Introduction

Ediacaran biota is a heterogeneous assemblage representing the earliest known communities of macroscopic organisms. Diverse Ediacaran fossil assemblages are coeval with the earliest phosphatized metazoan embryos (Xiao et al., 1998; but see Bailey et al., 2007; Xiao et al., 2007), the earliest undisputed traces of metazoan activities (Jensen, 2003), and the time of eumetazoan crown-group divergence estimated by some (but not all) molecular clocks (Peterson and Butterfield, 2005). Nonetheless, placing the Ediacaran morphologies into a metazoan phylogeny has been an enduring challenge to paleobiologists (Gehling, 1991; Fedonkin, 1992; Jenkins,

1992; Seilacher, 1992; Conway Morris, 1993; Runnegar, 1995; Budd and Jensen, 2000; Dzik, 2003; Narbonne, 2005; Fedonkin et al., 2007a). Earlier attempts to classify these organisms, based on superficial similarities with modern taxa, resulted in interpretations relating them with crown-group animals, specifically, colonial hydrozoans, scyphozoans, sessile colonial anthozoans, annelids, primitive arthropods, and echinoderms (Glaessner, 1984). Over time, various members of the Ediacaran biota have been regarded as representatives of a number of groups spanning several Kingdoms including prokaryotic colonies (Steiner and Reitner, 2001); eukaryotic microbial colonies (Grazhdankin and Gerdes, 2007); xenophyophoran protists (Zhuravlev, 1993; Seilacher et al., 2003); intermediates between plants and animals (Pflug, 1972); marine fungi (Peterson et al., 2003); lichens (Retallack, 2007); sponges (Gehling and Rigby, 1996); ctenophores (Dzik, 2002); and quasi-molluscs (Fedonkin and Waggoner, 1997; Fedonkin et al., 2007b). Seilacher famously proposed in 1989 and 1992 that Ediacaran biota represents an entirely extinct lineage of macroscopic organisms, the Vendobionta, which were based on a “quilted pneu” or air-mattress type modular construction and lacked any significant tissue or organ differentiation. To date, no agreement has been reached concerning either the biological affinities of the Ediacaran biota or the degree of its phylogenetic heterogeneity. It does appear, however, that most Ediacaran organisms lack any compelling similarities with metazoans (Seilacher, 1989, 1992; Retallack, 1994; Grazhdankin and Seilacher, 2002, 2005; Narbonne, 2004; Brasier and Antcliffe, 2004).

Morphological disparity

The overall taxonomic diversity of the Ediacaran biota is modest. A little over 250 species have been described, of which half represents valid taxa and the rest either pseudofossils or synonyms reflecting life stage and preservational variations. At least eight high-level taxonomic groups can be recognized demonstrating considerable disparity within the Ediacaran biota. (1) Rangeomorpha comprises of fusiform, foliate, and plumose organisms characterized by branched tubular structures (Narbonne, 2004). (2) Frondomorpha are composed of three distinct parts: a large, relatively flattened foliate section, a central stem, and a holdfast or rooting anchor (Laflamme and Narbonne, 2008); the fossil record of these organisms may be biased towards holdfasts that have a much higher preservation potential compared to foliate sections (Gehling et al., 2000; Hofmann et al., 2008). (3) Discoidal structures exhibit dense concentric rugae or broad concentric rings, occasionally with radial furrows (Grazhdankin and Gerdes, 2007). (4) Palaeopascichnida consist of series (sometimes multiple series and even foam-like aggregations) of sausage-shaped or globular chambers that are occasionally branching (Seilacher et al., 2003). (5) Tribrachiomorpha, a bizarre group of discoidal organisms with prominent three-fold symmetry

(Fedonkin, 1992). (6) Bilateromorpha, as the name says, comprise organisms with a bilaterally symmetric body (i.e., that consists of mirror image halves) (Fedonkin et al., 2007b). (7) Dickinsoniomorpha are flat and thin, at first glance bilaterally symmetric forms that consist of large number of segments, with one segment having a distinctive crescent shape and superficially resembling an arthropodal head-shield; the segments of the two sides do not line up perfectly along the midline, however, but are offset, are alternate, a kind of symmetry known as glide reflection (as opposed to mirror reflection symmetry) (Ivantsov, 1999, 2001, 2004, 2007). (8) Petalonamae, an imperfectly defined group dominated by serially quilted body plans, most exotic to mainstream biology; their mouldic preservation within sandstone is intriguing in that the specimens appear in variously curved and oriented shapes, approximately resembling internal moulds of pots and troughs (Pflug, 1972; Grazhdankin and Seilacher, 2002) (Figure 1).

Patterns of distribution

Ediacaran fossils have been documented globally within a discrete and well constrained interval of geological time between 575 and 544 Ma. Within this range, there is a clustering of three taxonomically distinct fossil assemblages: the Avalon-, Ediacara- and Nama-type biotas (Waggoner, 2003). The Avalon-type biota consists of rangeo- and frondomorphs. The Ediacara-type biota is the most diverse assemblage characterized by discoidal structures, frondo-, tribrachio-, bilatero-, and dickinsoniomorphs. The Nama-type biota is dominated by petalonamae. Palaeopascichnida are unique in that they occur in all three assemblages. The Avalon-, Ediacara-, and Nama-type biotas have been interpreted as evolutionary lineages, or biogeographic provinces, or preservational artefacts (Waggoner, 1999, 2003; Narbonne, 2005; Shen et al., 2008). It remains the case, however, that the Avalon-, Ediacara-, and Nama-type biotas were each confined to a certain habitat. These assemblages thus represent three principal ecotypes on a global scale, with Avalon-type biotas distributed in quiet waters on muddy substrates; Ediacara-type biotas inhabiting microbial substrates in shallow marine wave- and current-agitated settings; and Nama-type biotas found in extremely shallow-water river-mouth bar shoals (Grazhdankin, 2004) (Figure 2). Within each ecotype, species distribution and abundances exhibit extreme heterogeneity and patchiness on a population scale (Clapham and Narbonne, 2002; Clapham et al., 2003; Droser et al., 2006; Droser and Gehling, 2008). This may result from a variety of factors, including competitive interactions, initial distribution of colonists, history of disturbance, or underlying heterogeneity of the abiotic environment.

Preservation

Ediacaran organisms lack hard skeletons, yet the fossil preservation of their soft parts has almost no counterpart

Ediacaran Biota, Figure 1 Morphological disparity of the Ediacaran biota. (a) *Palaeopascichnus delicatus*, a member of Palaeopascichnida (hyporelief). (i) *Tribrachidium heraldicum*, a member of Tribrachiomorpha (hyporelief). (a), (c–i) Southeast White Sea area, Russia. (b), Podolia, Ukraine. Scale bar, 10 mm.

Ediacaran Biota, Figure 2 Patterns of distribution in the Ediacaran biotas. The Avalon-, Ediacara- and Nama-type biotas were each confined to a certain habitat.

to the classic examples in Phanerozoic (Conway Morris and Grazhdankin, 2005) (Figure 3). The preservation of Ediacaran fossils in coarse-grained sandstones might suggest that the organisms had an unusually tough integument (Seilacher, 1992), comparable with chitin of fungal cell walls (Retallack, 1994, 2007). A unique histology of Ediacaran bodies, such as presence of biomaterials indigestible for contemporary microorganisms or possible absence of degrading enzymes such as collagenase is sometimes invoked (Runnegar, 1991; Dzik, 1999). However, examples of Ediacaran fossils encrusted with aggregations of microcrystalline pyrite suggest that the Ediacaran tissues were not immune to microbial degradation after death, and that their decay fueled reduction of seawater sulfate. The most widely accepted view is that Ediacaran taphonomy represents a non-uniformitarian mode of preservation, associated with extensive pre-Cambrian microbial mat cover; certainly many of these fossils occur on microbially bound bedding surfaces characterized by finely-wrinkled, shagreen texture, and other microbially induced sedimentary structures (Gehling, 1991, 1999; Seilacher, 1999). Microbial mats and biofilms may have provided an adhesive surface to anchor benthic organisms during storms or inundation events, as well as protected the substrate from erosion. Storm deposits could

be subsequently recolonized by a new *microbial mat* that would in turn reduce particle and fluid mixing between oxic and anoxic layers in the sediment thereby facilitating early diagenesis. Sediments sealed by *microbial mats* would effectively act as closed dynamic systems of physical, chemical, and biochemical processes (see Chapter *Sediment Diagenesis – Biologically Controlled*). A smothered microbial mat itself could provide a template for precipitation of early diagenetic minerals and act as detailed “death-masks” of the associated Ediacaran corpses.

Biogeochemical perturbations

The sudden appearance and global dispersal of densely populated macroscopic communities of Ediacaran organisms would have had global ecological repercussions, and the Ediacaran period is noted for pronounced biogeochemical perturbations. Prior to appearance of the Ediacaran biota (~580 Myr ago), $\Delta\delta^{34}\text{S}$, the difference between coeval carbonate-associated sulfate and pyrite was conspicuously low while the ratios of “highly reactive iron” (i.e., the iron that is geochemically and biologically active during early sediment diagenesis) to total iron were high (Fike et al., 2006; Canfield et al., 2007), both indicating low ambient oxygen (at least locally).

Ediacaran Biota, Figure 3 *Charnia masoni* and *Mawsonites pleiomorphus* seen in four different taphonomic windows: rapid entombment in volcanic ash; authigenic carbonate cementation; siliciclastic microbial “death masks”; and taphonomic phantoms through deformation of associated carbonaceous films. Styles of mouldic preservation do not appear to be taxon selective, and therefore cannot alone be responsible for the morphological distinctiveness of the Ediacaran biota. (a), (c), Southeast White Sea area, Russia. (b), (d), (f), (h), Olenek Uplift, Russia. (e), Bonavista Peninsula, Newfoundland. (g), Chace Range, South Australia.

Following the appearance of the Ediacaran biota, highly reactive iron fell to essentially modern levels, $\Delta\delta^{34}\text{S}$ rose to $>46\text{‰}$ for the first time, and $\delta^{13}\text{C}_{\text{carb}}$ briefly dropped to an all time low of -15‰ PDB (though this was not tracked by $\delta^{13}\text{C}_{\text{org}}$). Current interpretation is that these shifts all mark a substantial rise of oxygen – from perhaps <10 to $>20\%$ PAL – and that the Ediacaran biota evolved immediately in response to the permissive ecology (Fike et al., 2006; Canfield et al., 2007). Alternatively, the rise of oxygen in Ediacaran time could be the consequence of a new-found sink for organic carbon, namely the production of abundant organic-carbon-adsorbing clay minerals – a consequence of newly evolved, soil-forming, terrestrial ecosystems (Kennedy et al., 2006). This, of course, echoes observations of pedogenic features (pertaining to processes of soil formation) in proximity to some Ediacaran fossils (Retallack, 1994, 2007). Thus, some biogeochemical perturbations during the Ediacaran period may have been the consequence of biotic evolution, rather than its cause (Butterfield, 2007).

Summary

Ediacaran biota is a geobiological phenomenon. From the evolutionary point of view it looks like an assortment of multiple experiments in multi-cellularity and/or

macroscopic size. In the ecological perspective, the Ediacaran biota witnessed what is arguably the earth’s most profound shift in ecosystem structure over the past 4 billion years, from an archaic world of limited morphological diversity and extreme evolutionary stasis to one of high diversity and rapid Phanerozoic-like turnover (Butterfield, 2007). The fossilized Ediacaran biota is seen through a unique taphonomic window, a product of intimate short-time relationships between macroscopic organisms and microbial substrates. Irrespective of whether the Ediacaran biota is related to Metazoa that define the Phanerozoic, it represents a key step in the origin of the modern biosphere.

ENDOLITHS

Bettina Weber, Burkhard Büdel

University of Kaiserslautern, Kaiserslautern, Germany

Definition

Endoliths: Organisms, growing in the interior of rocks. They are cryptoendoliths when growing within structural cavities, chasmoendoliths when inhabiting fissures and cracks of the rock, and euendoliths when actively penetrating rocky substrates (Golubic et al., 1981).

Endolithically growing organisms

The endolithic growth form occurs in a variety of organism groups comprising cyanobacteria, red and green algae, fungi, lichens and nonphotoautotrophic bacteria. Most endolithic habitats (if not all) accommodate several of these organism groups and are accompanied by a large variety of nonphotoautotrophic bacteria (McNamara et al., 2006).

Biogeography

Polar climate

Probably the best known endolithic communities, first described by Friedmann and Ocampo in 1976, are those of the Beacon Sandstone in the dry valleys of southern

Victoria Land, Antarctica. In his studies, Friedmann (1977, 1978) specified cryptoendolithic lichens forming multicolored zones several millimeters wide under the surface of sandstone rocks as well as chasmoendolithic lichens mainly growing in granitic rock substrates. Fertile stages of both allowed them to be identified as *Buellia* sp. (Friedmann et al., 1980) as well as species of the genera *Lecidea* and *Acarospora* (Friedmann, 1982). At a later stage, two eukaryotic communities (one lichen and one green algae – *Hemichloris* – dominated) plus three cyanobacterial communities (a red *Gloeocapsa*, a *Hormathonema-Gloeocapsa* and a *Chroococcidiopsis* community) were distinguished at this site (Friedmann et al., 1988).

Within a coastal desert at Marble Point, near the frozen Ross Sea, Friedmann (1982) identified heavy chasmoendolithic growth within weathered marble, consisting of filamentous green algae and cyanobacteria, being accompanied by colonies of colorless bacteria.

After the first discovery of endoliths in Antarctica, chasmoendolithic algae were also detected in other parts of the continent, such as the Vestfold Hills, Princess Elisabeth Land and Mawson Rock, and Mac. Robertson Land, where Broady (1981) found a variety of green algae and cyanobacteria within quartz stones, charnockites, gneisses and other rocks. Small endolithic colonies with cyanobacterial, bacterial and fungal components growing within a gypsum crust on the surface of sandstone boulders were discovered by Hughes and Lawley (2003) on Alexander Island, Antarctic Peninsula.

The structure of endolithic communities collected from Granite Harbour at the Ross Sea coast was studied by De Los Rios et al. (2003, 2005) utilizing scanning electron microscopy with backscattered electron imaging (SEM-BSE). They describe an intimate contact between the organisms and the surrounding substrate and in a subsequent study, combined with molecular analyses (De Los Rios et al., 2007), they were able to distinguish two different types of endolithic biofilms.

An extensive distribution of a chasmo- and cryptoendolithic cyanobacterial community, dominated by the unicellular cyanobacterium *Chroococcidiopsis* sp., was reported from granite rocks of an area extending at 600 m elevation at Mt. Falconer, in the McMurdo Dry Valleys (Büdel et al., 2008; Figure 1a–c). The authors found that community to be highly active due to regular dewfall on the rock surface. Radiocarbon dating indicated that the community is by far younger than those reported from a 1,000 m higher elevation by Bonani et al. (1988).

Besides Antarctica, cryptoendolithic habitats were also discovered in the Canadian High Arctic (Omelson et al., 2006), hosting an assemblage of cyanobacteria, algae, fungi and heterotrophic bacteria within sandstone rocks.

Arid and semiarid climate

Endolithic cyanobacteria are known to occur in a variety of habitats within hot and tropical regions

Biogeography

Polar climate

Probably the best known endolithic communities, first described by Friedmann and Ocampo in 1976, are those of the Beacon Sandstone in the dry valleys of southern

Victoria Land, Antarctica. In his studies, Friedmann (1977, 1978) specified cryptoendolithic lichens forming multicolored zones several millimeters wide under the surface of sandstone rocks as well as chasmoendolithic lichens mainly growing in granitic rock substrates. Fertile stages of both allowed them to be identified as *Buellia* sp. (Friedmann et al., 1980) as well as species of the genera *Lecidea* and *Acarospora* (Friedmann, 1982). At a later stage, two euaryotic communities (one lichen and one green algae – *Hemichloris* – dominated) plus three cyanobacterial communities (a red *Gloeocapsa*, a *Hormathonema-Gloeocapsa* and a *Chroococcidiopsis* community) were distinguished at this site (Friedmann et al., 1988).

Within a coastal desert at Marble Point, near the frozen Ross Sea, Friedmann (1982) identified heavy chasmoendolithic growth within weathered marble, consisting of filamentous green algae and cyanobacteria, being accompanied by colonies of colorless bacteria.

After the first discovery of endoliths in Antarctica, chasmoendolithic algae were also detected in other parts of the continent, such as the Vestfold Hills, Princess Elisabeth Land and Mawson Rock, and Mac. Robertson Land, where Broady (1981) found a variety of green algae and cyanobacteria within quartz stones, charnockites, gneisses and other rocks. Small endolithic colonies with cyanobacterial, bacterial and fungal components growing within a gypsum crust on the surface of sandstone boulders were discovered by Hughes and Lawley (2003) on Alexander Island, Antarctic Peninsula.

The structure of endolithic communities collected from Granite Harbour at the Ross Sea coast was studied by De Los Rios et al. (2003, 2005) utilizing scanning electron microscopy with backscattered electron imaging (SEM-BSE). They describe an intimate contact between the organisms and the surrounding substrate and in a subsequent study, combined with molecular analyses (De Los Rios et al., 2007), they were able to distinguish two different types of endolithic biofilms.

An extensive distribution of a chasmo- and cryptoendolithic cyanobacterial community, dominated by the unicellular cyanobacterium *Chroococcidiopsis* sp., was reported from granite rocks of an area extending at 600 m elevation at Mt. Falconer, in the McMurdo Dry Valleys (Büdel et al., 2008; Figure 1a–c). The authors found that community to be highly active due to regular dewfall on the rock surface. Radiocarbon dating indicated that the community is by far younger than those reported from a 1,000 m higher elevation by Bonani et al. (1988).

Besides Antarctica, cryptoendolithic habitats were also discovered in the Canadian High Arctic (Omelson et al., 2006), hosting an assemblage of cyanobacteria, algae, fungi and heterotrophic bacteria within sandstone rocks.

Arid and semiarid climate

Endolithic cyanobacteria are known to occur in a variety of habitats within hot and tropical regions

Endoliths, Figure 1 (a) Granite rock boulders as endolithic habitat, Mt. Falconer, McMurdo Dry Valleys, Antarctica. (b) Uncovered endolithic community, Mt. Falconer, Antarctica. Red scale = 4 cm. (c) Endolithic *Chroococcidiopsis* sp., Mt. Falconer, Antarctica. (d) *Synechococcus elongatus* endolithic in red sandstone (arrow), Spessart-Midlands, Germany. (e) *Hymenelia prevostii* has an oval, crustose, whitish-gray thallus. Brownish-pink apothecia are sunk into the thallus, separated from it by a narrow crack. The cross-fracture (inlet) is characterized by algal clusters of an elongated shape. (f) *H. coerulea* is characterized by its bluish to bluish-gray thallus that in some areas remains almost completely below the surface of the substrate. The mostly rimless apothecia are nonpruinose, small (0.2–0.4 mm) and are often situated on small elevations within the limestone. The cross-fracture (inlet) is characterized by smaller algal clusters (compared to *H. prevostii*) of a roundish shape; image taken by fluorescence microscopy, accomplished by mercury arc lamp activated in the blue region. (g) Exfoliation pattern of the South African Tshipise Sandstone along the growth zone of the organisms (green, arrows); the loosened exfoliative flakes are transported away by flowing water. (h) Geological thin section of the Tshipise Sandstone. Within the growth zone of the organisms, dissolution of the binding material, etch marks (arrow) on the quartz grains, and precipitation of calcium carbonate (arrow) are observed.

throughout the world. On the hillsides of the Negev Highlands, Friedmann et al. (1967) and later Danin and Garty (1983) observed both chasmoendolithic and coccoid euendolithic cyanobacteria within different rock types. A widespread and relatively uniform distribution of endolithic algae and cyanobacteria within sandstones was

discovered by Bell et al. (1986), along a transection covering both temperate and semidesert biomes of northern Arizona, southern Utah, and western New Mexico. Büdel and Wessels (1991) identified chasmoendolithic, cryptoendolithic, and hypolithic cyanobacteria within semiarid to arid regions of Africa, North America, Australia, and

Europe. The genus *Chroococcidiopsis* was found to occur almost worldwide within the cryptoendolithic habitat of hot deserts (Büdel, 1999; Weber et al., 1996, Figure 1c). Even within halite rocks in the hyperarid core of the Atacama Desert, this genus was observed to grow together with heterotrophic bacteria (Wierzchos et al., 2006).

In recent studies, endolithic cyanobacteria were also identified by means of molecular methods, like the endolithic communities within travertine deposits in Yellowstone National Park, which turned out to contain a variety of different cyanobacteria, including several new lineages (Norris and Castenholz, 2006). The endolithic communities in limestone from a Maya archaeological site only inhabited photosynthetically inactive bacteria, with cyanobacteria being restricted to the epilithic growth form (McNamara et al., 2006).

Descriptions of endolithic lichens within hot and tropical regions are much rarer. Wessels and Schoeman (1988) observed the endolithically growing *Lecidea* aff. *sarcogynoides* Koerb. on Clarens sandstone within the Golden Gate Highlands National Park, South Africa. The endolithic Sonoran Desert lichen *Verrucaria rubrocincta* Breuss was found to occur locally in abundance in caliche plates of open desert pavements (Bungartz et al., 2004).

Temperate climate

Endolithically growing organisms were first described by Bachmann (1890), who recognized the endolithic growth of *Verrucaria calciseda* DC. and also other species (e.g., *Sarcogyne pruinosa* Smft., *Aspicilia flavida* Hepp.) somewhat later (1892), by studying microscopical thin sections of local limestone samples. The chasmoendolithic growth of lichens, like *Aspicilia gibbosa* Ach., along mica minerals was first detected by Bachmann (1904), whereas Diels (1914) described a completely chasmoendolithic formation of algae inhabiting dolomite rocks in the Alps.

In a recent study, Hoppert et al. (2004) investigated the colonization of limestone in the Dachstein area of the Alps after continuous retreat of two glaciers, observing the endolithic hyphae of black fungi (Aureobasidiomycetes) as first colonizers 2 years after exposition of the rock, whereas the first green algae appeared between 5 and 12 years after exposure. Exposure times between 30 and 100 years resulted in macroscopically visible biofilms being dominated by endolithically growing lichens.

In contrast to that, endolithic growth below temperate-zone cliffs of the Niagara Escarpment, Canada, was only present under 6% of the surface area (Matthes-Sears et al., 1997), whereas the majority of the surface was covered by epilithic growth.

Aquatic habitats

Even in the coastal areas of marine environments, a variety of endolithically growing organisms are known to occur. At the limestone coasts of the northern Adriatic

near Rovinj, Schneider (1976) identified a variety of cyanobacteria and lichens. Le Campion-Alsumard (1979) described ten different species of cyanobacteria, which were often associated with green algae, fungi, and bacteria, revealing bathymetric distribution patterns up to 80 m below sea level in the region of Marseille.

In Shark Bay, western Australia, lithified stromatolites, which were formed by the coccoid cyanophyte *Entophysalis major* Ercegović, were described to be colonized by a thin bluish-black layer of predominantly epilithic thalli of the cyanobacterium *Hormathonema violaceo-nigrum* Ercegović, which sent short endolithic filaments about 50 μm deep into the substrate (Golubic, 1983). Papineau et al. (2005) utilized molecular techniques to characterize a diverse community consisting of bacteria and archaea with only a small fraction of cyanobacteria within this endolithic habitat.

Recently, endolithic microbial communities have been discovered even in the extremely acidic (pH = 1) geothermal environment of Yellowstone National Park (Walker et al., 2005), where an acidophytic eucaryotic red alga (*Cyanidium* sp.) and actinobacteria (*Mycobacterium* spp.) made up the vast majority of the community. In contrast to that, geothermal rocks in the area of Rotorua, New Zealand, were found to be inhabited by a variety of endolithic cyanobacteria with the red algal genus *Cyanidium* occurring but playing only a minor role (Gaylarde et al., 2006).

In a pH-neutral and oxygen-rich creek in the midland area Spessart (Germany), the cyanobacterium *Synechococcus elongatus* Näg. was found to be growing cryptoendolithically within the bleached sandstone (Büdel et al., 1991, Figure 1d).

Advantages of endolithic growth

Light

It appears quite obvious that the overlying rock substrate effectively shields light from the endolithic organisms. Matthes et al. (2001) experienced an exponential decrease of light intensity in limestone with increasing depth and, using a normal photosensor, they measured 1% of the incoming light 1 mm within the dry substrate. Friedmann and Ocampo-Friedmann (1984) found that in a dry stage about 0.1% of the incoming light reached the upper level of the lichen zone, compared to about 1% in a wet stage. Weber et al. (1996) however explain that due to light dispersal and reflectance within the rock, scalar irradiance, measuring light intensity at an angle of nearly 360°, has to be investigated. By inoculating sterile quartz sand with cyanobacterial cultures, we were able to show that at higher light intensities, colonies of *Chroococcidiopsis* sp. (strain 90.1 and 90.5; culture collection of Department of Plant Ecology and Systematics, University of Kaiserslautern) and *Nostochopsis lobatus* (strain 92.1) settled significantly deeper within the substrate (Spearman's rho, strain 90.1: $n = 48$, $r_s = 0.442$, $p = 0.002$; strain 90.5: $n = 48$, $r_s = 0.752$, $p < 0.001$; strain 92.1: $n = 30$, $r_s = 0.494$,

Endoliths, Figure 2 Experimental setup with cyanobacterial cultures being inoculated on petri dishes with sterile quartz sand. After 5 months of growth under different light intensities, each sample was measured at six spots to obtain mean values and standard deviations. With increasing light intensity, each single strain as well as the organisms as one group settled significantly deeper within the substrate (Spearman's rho, strain 90.1: $n = 48$, $r_s = 0.442$, $p = 0.002$; strain 90.5: $n = 48$, $r_s = 0.752$, $p < 0.001$; strain 92.1: $n = 30$, $r_s = 0.494$, $p < 0.006$; all strains: $n = 126$, $r_s = 0.542$, $p < 0.001$).

$p < 0.006$; all strains: $n = 126$, $r_s = 0.542$, $p < 0.001$; Figure 2), strongly supporting the light shielding hypothesis. Measuring the light intensities needed by alpine endolithic lichens to reach the compensation and saturation point of photosynthesis, Weber et al. (2007) found relatively high cardinal points, also ascribing this to the light protecting properties of the limestone within this high light environment.

Temperature

In the cold deserts of Antarctica, Friedmann and Ocampo-Friedmann (1984) reported the endolithic environment to be much less affected by rapid temperature oscillations and coherent freezing and thawing cycles that occur at the rock surface as a result of the frequent gusts of katabatic winds. Friedmann (1980) measured temperature differences up to 7 K between the rock surface and 3 cm within the rock, while Friedmann et al. (1981) registered more balanced and up to 3 K higher temperatures within the lichen zone, as compared to the rock surface.

In the High Arctic, Omelon et al. (2006) measured only minor differences (0.1–0.3 K) between the mean temperature values and no major differences between the

minimum and maximum temperature values (0–1.1 K) at the rock surface and 5 mm below on a south-facing outcrop.

Similarly, Weber et al. (1996) measured the absolute temperature maxima to be only 1°C lower within the endolithic habitat of a South African sandstone plateau, as compared to the rock surface.

In summary, the temperature effect seems to be important in some Antarctic habitats where the endolithic growth prevents the organisms from frequent freezing and thawing. In warm climates, however, no major effect can be concluded from the minor temperature differences.

Humidity

Both in hot and cold deserts, porous rocks like sandstone are expected to function as a substantial water reservoir that allows the organisms to be active over a by far longer timespan than on the rock surface (Friedmann et al., 1981; Weber et al., 1996). The latter authors measured water content values between 4% and 79% in the upper 3 cm of the sandstone at the end of the dry season, and found these water contents to be positively correlated with the N- and C-content of the sandstone samples (Spearman's

rho; nitrogen: $n = 32$, $r_s = 0.585$, $p < 0.001$; carbon: $n = 32$, $r_s = 0.685$, $p < 0.001$). Similarly, Bell (1993) measured the internal relative humidity values within colorized sandstone of the Colorado Plateau to be usually above 80% and never below 60%, regardless of the season. In contrary to that, Friedmann (1980) described the water content of sandstone samples from Antarctica, from the American desert and from the Sinai Peninsula to be remarkably similar with only 0.1–0.2% of the weight of the rock. He expected this quantity of moisture to be sufficient for a nearly saturated atmosphere within cold desert rocks, whereas in hot deserts they would result in low humidity values. Büdel et al. (2008) also experienced the availability of water to be one of the most critical factors within Antarctic endolithic habitats. They observed that regular dewfall can occur by a temperature inversion between the rock surface and air, thus leading to dew precipitation on the rock surface. The penetration depth of the water was also found to be critical for the depth of growth of endolithic cyanobacteria.

In summary, elevated humidity values are widely accepted to favor the endolithic habitat, whereas the actual humidity values dependent on the climatic conditions have only rarely been measured within the different biomes.

Grazing organisms

A less frequently named potential advantage is the endolithic shelter against grazing organisms. Schneider (1976) observed intense grazing of epilithic algae and cyanobacteria along the limestone coast of the Adria by gastropods, whereas endolithic organisms were shielded within the substrate. Tretiach (1995) described frequent grazing marks on epilithic lichens, whereas endolithic lichens that were particularly frequent in deeply shaded humid habitats revealed hardly any grazing marks by arthropods, gastropods or other small animals.

Therefore, in certain habitats, endolithic growth may be an effective shelter against grazing organisms, whereas it is not considered to be a major controlling factor.

Weathering mechanisms and biosignatures

Weathering features connected with the endolithic growth of organisms were observed as early as in 1880, when Sollas described the chemical weathering effect of the

endolithic lichen *Verrucaria rupestris* Schrad. (now *Verrucaria muralis* Ach.) growing on limestone. Bachmann (1892) observed that fungal hyphae and even fruiting bodies (e.g., apothecia) were able to grow within hard limestone rocks, and concluded that the hyphae secrete a substance dissolving the rock. In 1916, he was the first to propose the widely accepted weathering mechanism within carbonate rocks: the active organisms release CO_2 , which forms carbonic acid (H_2CO_3) in a humid environment that in turn, together with the calcium carbonate of the rock, forms water-soluble bicarbonate.

During the following decades there have been several descriptions of weathering patterns on limestone (e.g., Degelius, 1962; Le Campion-Alsumard, 1979; Danin et al., 1983; Gehrmann et al., 1992) and even stromatolites were observed to be weathered by the partly epi- and endolithically growing cyanobacterium *Hormathonema violaceo-nigrum* (Golubic, 1983). Weber et al. (Respiration-Induced Weathering Patterns of Two Endolithically Growing Lichens) studied the weathering patterns of two endolithic lichen species (*Hymenelia prevostii* (Duby) Krempelh. and *H. coerulea* (DC.) Massal., Figure 1e and f) in the Limestone Alps and observed the same general weathering pattern. However, *H. prevostii* revealed to develop more than twofold the biomass compared to *H. coerulea* and to modify a significantly wider zone within the substrate (Figure 1e and f; Table 1).

Pohl and Schneider (2002), however, described an overall protective effect of endoliths on carbonate rocks, since after primary colonization they did not observe a continuous loss of material but an internal recycling within the biofilm. Together with the coauthors, they even saw the upper substrate layer, which is usually impregnated by extracellular polymeric substances (EPS) of cyanobacteria, as a protective shield and recognized a stabilizing effect by the tightly woven internal cellular network of the organisms.

Weathering traces on silicate rocks (garnets) were also recognized already a long time ago (Bachmann, 1911), but weathering marks on quartz crystals were unknown

Endoliths, Table 1 Growth characteristics and weathering patterns of *Hymenelia prevostii* and *H. coerulea*. Differences of mean values were tested for statistical significance by *T*-test (chlorophyll content) and Mann-Whitney *U*-test (depth of beginning of algal layer and unaltered substrate)

Growth characteristics	<i>Hymenelia prevostii</i>	<i>Hymenelia coerulea</i>	Statistical significance
Chlorophyll content (mg chl $a + b \text{ m}^{-2}$)	322.4 ± 39.4 ($n = 3$)	141.7 ± 2.2 ($n = 2$)	$T = 6.469$, $p = 0.022$
Depth of beginning of algal layer (mm)	0.102 ± 0.034 ($n = 40$)	0.058 ± 0.019 ($n = 40$)	$U = 213.5$, $p < 0.001$
Depth of beginning of unaltered substrate (mm)	0.366 ± 0.091 ($n = 40$)	0.179 ± 0.036 ($n = 40$)	$U = 11.5$, $p < 0.001$

at that time. A distinctive weathering pattern of sandstone was discovered by Friedmann (1982), who described a dissolution of the cementing substance along the growth zone of endolithic lichens in the Antarctic cold desert. A very similar weathering pattern was observed by us (Weber et al., 1996) in the South African Tshipise Sandstone, where endolithic cyanobacteria caused the exfoliation of the substrate along the growth zone (Figure 1g). Such an exfoliation of sandstone was also described by Wessels and Schoeman (1988) for the endolithically growing lichen *Lecidea* aff. *sarcogynoides*. Since the silicate weathering could not be explained by an acidification as that of limestone, the driving mechanism was unknown until recently, when we could show that an alkalization process during photosynthesis was responsible (Büdel et al., 2004). This alkalization was shown to be responsible for a dissolution of the binding material, etch marks on the quartz grains, and a precipitation of calcium carbonate within the studied sandstone (Figure 1h), which resulted in the previously described exfoliation of the sandstone.

The formation of minerals, which could serve as biosignatures within rock deposits was already described in 1916 when Bachmann explained the deposition of calcium oxalate by endolithic cyanobacteria within limestone. Friedmann and Weed (1987) observed the formation of quartz rhinds on top of the endolithic organisms within the Beacon Sandstone, South Africa. This dense crystalline layer above the organisms was also recognized by us, but as stated earlier, we also observed the precipitation of calcium carbonate within the growth zone of the cyanobacteria (Figure 1h; Büdel et al., 2004).

The preservation of cell structures in the form of fossil endoliths is known from the silicified stromatolithic crusts of the 1,500–1,700 Ma old Dahong Yu Formation in China (Zhang and Golubic, 1987). But also ooid assemblages of several *Eohyella* species within 800 Ma old rocks were found to be comparable to modern ooids of the Bahama Bank and the Arabian Gulf (Knoll et al., 1986). Body fossils of endolithic bangiacean rhodophytes were found in sediments that are 420 Ma old (Kamierczak and Golubic, 1976), whereas Wierzchos et al. (2005) described the recent formation of cell-shaped structures within the sandstones of Antarctica. The latter authors propose these structures to be important markers in the search for former life on Mars. Golubic and Schneider (2003) as well as Banfield et al. (2001) point out that the activity of endolithic organisms left a rich fossil record of boring and mineralization patterns behind, which reveal the nature of palaeoenvironmental conditions under which they lived.

Conclusions

Endolithic growth is realized by a variety of organisms, such as cyanobacteria, algae, lichens, fungi, and bacteria, and occurs in various habitats all over the world. The advantages of endolithic growth are multifarious, like the

shield from high light intensities or grazing organisms or the occurrence of more favorable temperature and humidity conditions, with their relevance being variable within the different habitats. The endolithic organisms are known to have weathering effects on both calcareous and siliceous substrates with different underlying processes. The weathering marks and also newly formed minerals can serve as biosignatures, which allow to draw conclusions on endolithic growth in former times or on other planets.

ENDOSYMBIOSIS

Endosymbiosis is a close, prolonged physical and/or metabolic association between distinct organisms, one of which lives inside the body of the other, either within its cells or in extracellular spaces.

Synonyms

Excreted/secreted enzymes; Extracellular enzymes

Definition

Exoenzyme is an enzyme produced by a microorganism that secreted into the environment that is capable of degrading insoluble polymers.

Introduction

Osmotroph organisms, that is, archaea, bacteria, and fungi, are not able to ingest particulate matter directly but rather have to obtain nutrients through the active uptake of soluble compounds across their cell membrane. Organic polymers such as proteins, cellulose and hemicelluloses, lignin, chitin, starch, and lipids can only serve as sources for energy and anabolic processes if they are degraded into small, transportable molecules by secreted hydrolytic enzymes, collectively termed “exoenzymes.” The most relevant exoenzyme classes, their impact on biogeochemical cycles, symbiotic/pathogenic interactions and major biotechnological applications are summarized in the following paragraphs.

Exoenzymes – an overview

[Figure 1](#) illustrates the most relevant microbial exoenzymes and their substrates. Their catalytic mechanisms as well as selected review articles describing the respective enzymes in detail are shown in [Table 1](#). [Figure 2](#) summarizes the impact of microbial enzymes on environmental processes and their application in biotechnology; both aspects are discussed in detail in the following paragraphs.

Exoenzymes and their impact on environmental processes

Prokaryotic and eukaryotic microorganisms are one of the main driving forces of biogeochemical cycles as they can decompose virtually all natural compounds, thereby exerting a lasting effect on biosphere and climate (Madigan et al., 2008). Archaea, bacteria, and fungi are the only living agents that are capable of regenerating essential elements such as carbon, sulfur, nitrogen, and iron by decomposing dead organic matter. Moreover, some microorganisms are able to degrade plastics, particularly biopolymers, and highly complex xenobiotics such as crude oil, and thus contribute significantly to the cleanup or detoxification of environmental pollutants (bioremediation; Knackmuss, 1996).

Synonyms

Excreted/secreted enzymes; Extracellular enzymes

Definition

Exoenzyme is an enzyme produced by a microorganism that secreted into the environment that is capable of degrading insoluble polymers.

Introduction

Osmotroph organisms, that is, archaea, bacteria, and fungi, are not able to ingest particulate matter directly but rather have to obtain nutrients through the active uptake of soluble compounds across their cell membrane. Organic polymers such as proteins, cellulose and hemicelluloses, lignin, chitin, starch, and lipids can only serve as sources for energy and anabolic processes if they are degraded into small, transportable molecules by secreted hydrolytic enzymes, collectively termed “exoenzymes.” The most relevant exoenzyme classes, their impact on biogeochemical cycles, symbiotic/pathogenic interactions and major biotechnological applications are summarized in the following paragraphs.

Exoenzymes – an overview

[Figure 1](#) illustrates the most relevant microbial exoenzymes and their substrates. Their catalytic mechanisms as well as selected review articles describing the respective enzymes in detail are shown in [Table 1](#). [Figure 2](#) summarizes the impact of microbial enzymes on environmental processes and their application in biotechnology; both aspects are discussed in detail in the following paragraphs.

Exoenzymes and their impact on environmental processes

Prokaryotic and eukaryotic microorganisms are one of the main driving forces of biogeochemical cycles as they can decompose virtually all natural compounds, thereby exerting a lasting effect on biosphere and climate (Madigan et al., 2008). Archaea, bacteria, and fungi are the only living agents that are capable of regenerating essential elements such as carbon, sulfur, nitrogen, and iron by decomposing dead organic matter. Moreover, some microorganisms are able to degrade plastics, particularly biopolymers, and highly complex xenobiotics such as crude oil, and thus contribute significantly to the cleanup or detoxification of environmental pollutants (bioremediation; Knackmuss, 1996).

Exoenzymes and their impact on environmental processes

Prokaryotic and eukaryotic microorganisms are one of the main driving forces of biogeochemical cycles as they can decompose virtually all natural compounds, thereby exerting a lasting effect on biosphere and climate (Madigan et al., 2008). Archaea, bacteria, and fungi are the only living agents that are capable of regenerating essential elements such as carbon, sulfur, nitrogen, and iron by decomposing dead organic matter. Moreover, some microorganisms are able to degrade plastics, particularly biopolymers, and highly complex xenobiotics such as crude oil, and thus contribute significantly to the cleanup or detoxification of environmental pollutants (bioremediation; Knackmuss, 1996).

Exoenzymes, Figure 1 Degradation of insoluble polymers by secreted microbial enzymes. Note that the bacterial cell represents microbes in general.

Symbiotic interactions between microorganisms and animals (e.g., termites and ruminants) owe a great debt to the beneficial activities of microbial exoenzymes (Madigan et al., 2008). For example, a varied intestinal flora of bacteria, fungi (and protozoa), enable herbivores to digest cellulose and other plant polysaccharides. A vital part of human nutrition thereby directly stems from this exoenzymatic activity in the intestinal tracts of livestock and other ruminants, converting low-energy plant foods into high-energy foods such as milk, dairy products, and meat. On the other hand, uncontrolled microbial growth together with the production of hydrolytic enzymes such as proteases, lipases, and cell-wall degrading enzymes also destroys vast amounts of food and can even lead to food-borne infections or poisoning.

In deleterious host-pathogen interactions, exoenzymes produced by the pathogens may act as virulence factors (Madigan et al., 2008). Prominent examples for such

pathogenic enzymes are (a) hyaluronidases and coagulases produced by human and animal pathogens that degrade the intercellular matrix component hyaluronic acid or dissolve fibrin clotting, respectively, enabling them to invade and colonize host tissues, or (b) pectinases and cellulases produced by plant pathogens that break up cell walls and facilitate invasion and degradation of living plants.

Exoenzymes – nature's biotechnology tools

Microbial enzymes have served humankind since pre-historic times in the traditional production and conservation of food such as wine and cheese. However, enzymes as molecular tools were not discovered until the second half of the nineteenth century and have since been extensively used in various industries (Damhus et al., 2008). Classical chemical transformation processes have various inherent drawbacks, for example, poor product yields, high energy costs, harsh and hazardous reaction conditions and unwanted, partly harmful by-products. In

Exoenzymes, Table 1 Exoenzymes, substrates, and reaction mechanisms

Enzyme (subclasses)	Substrate	Catalytic mechanism	Reviewed in
Amylases α -Amylases β -Amylases Pullulanases Isoamylases Glucoamylases	Starch: mixed storage polymer consisting of amylose and amylopectin	Hydrolysis of α -1,4- or α -1,6-glycosidic bonds	Vihinen and Mäntsälä (1989)

Hyaluronidases	Hyaluronic acid, a major constituent of the interstitial barrier	Hydrolysis of 1,4- β -D-glycosidic bonds	Stern and Jedrzejewski (2006)
Ligninases Various peroxidases Laccases Accessory enzymes	Lignin: second most abundant structural polymer in plants, highly recalcitrant to degradation	Oxidation of various phenolic and non-phenolic lignin compounds	Wong (2009)
Lipases	Lipids: long-chain acylglycerols	Hydrolysis or synthesis of ester bonds	Jaeger and Eggert (2002)
Pectinases Polygalacturonases Pectin esterases Pectin lyases Pectate lyases	Pectin: polygalacturonic acid polymer present in plant primary cell walls and middle lamellae	Hydrolysis of α -1,4-galactosiduronic bonds	Alkorta et al. (1998)
Proteases Endoproteases Exoproteases Coagulases	Proteins or peptides: amino acid polymers Fibrinogen	Hydrolysis of peptide bonds Conversion of fibrinogen to fibrin	Rao et al. (1998) Rivera et al. (2007)

contrast, enzymatic reactions proceed under mild conditions are highly specific and involve very fast reactions. Moreover, enzymes contribute to sustainable development as they can be isolated from microorganisms which are cultured using primarily renewable resources (Damhus et al., 2008).

Modern advancements in biotechnology, especially in the field of molecular genetics and protein engineering, have brought the application of a wide variety of biocatalysts to many different industries (Figure 2 and Table 2): (a) amylases, proteases, lipases, and pectinases are used in the food industry, ranging from traditional applications in wine and beer production, cheese ripening, baking, but also for fruit juice clarification and sweetener production; (a) xylanases, cellulases, and amylases are employed in the paper industry for bleaching, recycling, and coating; (c) lipases, proteases, amylases, and cellulases are added to laundry and automated dishwashing detergents to improve cleaning performance and reduce energy and water consumption; (d) in the textile industry cellulases, laccases, and peroxidases are used for

bio-bleaching of jeans fabrics and cellulases/proteases for bio-polishing of cotton fabrics, wool and silk products; (e) amylases and cellulases are employed for biofuel production from starch- and cellulose-containing raw materials.

Summary

Microorganisms are able to degrade all naturally occurring organic compounds and also certain xenobiotic substances that persist in oxic environments and thereby deserve to be considered omnipotent. To this end, archaea, bacteria, and fungi secrete specific enzymes, the so-called “exoenzymes” into the immediate surroundings that act to break down their substrates in part or even up to complete mineralization. Exoenzymes are thus of great importance for elemental recycling processes within biogeochemical cycles, yet they also contribute substantially to symbiotic or pathogenic interactions between microbes and higher organisms and are furthermore useful catalysts for various biotechnological and industrial applications.

Definition

Extracellular polymeric substances (EPS) are molecules having a range of sizes, compositions, and chemical properties that are produced and secreted by bacteria and other microorganisms, and contribute to the cell adaptability, resiliency, and functional roles in environments.

Capsule refers an extracellular matrix that immediately surrounds a cell.

Biofilms refer to attached microbial cells surrounded within a matrix of EPS.

Introduction

It has been realized for a long time that microbial organisms may exist as free-living individuals as well as in groups, attached to surfaces or to each other, and that under many conditions cells often prefer to attach to surfaces. Under the fluctuating, often less-predictable conditions of natural systems, such attachment may confer advantages and a certain degree of stability to cells. It is now realized that most bacteria and other microorganisms (e.g., cyanobacteria, archaea, diatoms) exist as attached “biofilms.” The biofilm consists of microbial cells that have attached to a surface (or aggregated), and have surrounded themselves within a gelatinous matrix of *EPS*, and may exhibit varying degrees of community structure (Decho, 1990). Biofilm formation appears to be a common microbial process that occurs under a wide range of conditions and environments, and whose influences span aquatic, terrestrial, the epi- and

Definition

Extracellular polymeric substances (EPS) are molecules having a range of sizes, compositions, and chemical properties that are produced and secreted by bacteria and other microorganisms, and contribute to the cell adaptability, resiliency, and functional roles in environments.

Capsule refers an extracellular matrix that immediately surrounds a cell.

Biofilms refer to attached microbial cells surrounded within a matrix of EPS.

Introduction

It has been realized for a long time that microbial organisms may exist as free-living individuals as well as in groups, attached to surfaces or to each other, and that under many conditions cells often prefer to attach to surfaces. Under the fluctuating, often less-predictable conditions of natural systems, such attachment may confer advantages and a certain degree of stability to cells. It is now realized that most bacteria and other microorganisms (e.g., cyanobacteria, archaea, diatoms) exist as attached “biofilms.” The biofilm consists of microbial cells that have attached to a surface (or aggregated), and have surrounded themselves within a gelatinous matrix of *EPS*, and may exhibit varying degrees of community structure (Decho, 1990). Biofilm formation appears to be a common microbial process that occurs under a wide range of conditions and environments, and whose influences span aquatic, terrestrial, the epi- and

endo-biont communities of plants and animals, and as well as disease and health processes (Stoodley et al., 2002).

The EPS matrix

One major change that occurs upon attachment to a surface and the formation of a biofilm is the secretion of EPS. The EPS consist of a wide range of molecules that confer different physical/chemical properties and adaptations for cells. The EPS matrix consists of molecules having a range of molecular sizes and conformations. The physical structure of natural EPS is poorly understood but may contain waterchannels, physical forms ranging from tight, dense gels to looser, dispersed slimes, whose EPS diffusivities (i.e., the ability of molecules to diffuse through EPS) may vary considerably. This provides cells with the potential capability to bind and sequester important ions, nutrients, and other molecules, and create strong biogeochemical gradients over small (i.e., micrometer) spatial distances. Cells may additionally surround themselves with EPS *capsules*. Together, EPS form the three-dimensional architecture from which cells may structure interactions, and even construct organized macrostructures.

EPS is an operational designation that refers to the milieu of relatively “large” molecules contained in the extracellular matrix in proximity to cells. In the past, cold-ethanol precipitations were used to separate the large polysaccharide-rich fraction of EPS from other molecules in the extracellular matrix. It is now realized, however, that a host of other molecules (e.g., proteins, lipids, and even DNA, etc.) may be present in the extracellular matrix. It is now realized that in natural biofilms, the polysaccharide fraction represents only a (small) subset of a more diverse EPS matrix. It is now realized that in some natural systems, a large portion of the EPS cannot be defined as a protein, carbohydrate, or lipid, and hence does not conveniently fit into classical chemical categories.

Initially, EPS was largely considered to be a matrix of “*exopolysaccharides*” (i.e., extracellular polysaccharides); and implied that the terms *EPS* and *exopolysaccharides* were synonymous. However, this was, in part, based on the specific carbohydrate-focus of investigators at the time, and further due to an artifact of carbon-rich culture conditions that were needed to grow bacteria and produce abundant quantities of exopolysaccharide. Much has been learned about polysaccharide chemistry from these important seminal studies (for an early review see Sutherland, 1982).

Currently, it is assumed that EPS contains proteins that may act as both structural components for the EPS matrix and as extracellular enzymes. More recently, deoxyribonucleic acids (DNA) have been abundantly found in the EPS of certain bacteria grown in culture, and in EPS extracted from natural microbial communities. While it is likely that some of this DNA may originate from the lysis of bacteria cells, there is growing evidence that bacteria may actively secrete DNA as part of the EPS. This has important implications for understanding DNA as solely an information molecule. Also, recent

interest has centered on the occurrence of very refractory forms of proteins, called “amyloid proteins” in EPS. These heavily cross-linked proteins have been previously linked to disease processes in humans. In the EPS matrices of microbial communities, such amyloid proteins may provide a refractory “rebar” to resist degradation of the EPS.

Careful examinations of the EPS matrix are now being conducted using specialized equipment such as atomic force microscopy (AFM), nuclear magnetic resonance (NMR) spectroscopy, and confocal scanning laser microscopy (CSLM) in order to image and characterize the matrix under in situ conditions (Figure 1).

Roles of EPS in geobiology

A great deal of interest is developing in the role of EPS as it influences the broader area of geobiology. This interest centers on the role of biologically produced molecules in mineral formation. Certain molecules may directly or indirectly influence how minerals are formed through precipitation events.

The role of EPS in this process may be twofold (Dupraz et al., 2009). When EPS is newly secreted by microorganisms, certain functional groups (e.g., carboxyls) on the EPS may efficiently sequester Ca^{++} ions by forming bidentate bridges between adjacent EPS molecules, and thus inhibit complexation with available carbonate anions, and precipitation. However, partial degradation

Extracellular Polymeric Substances (EPS), Figure 1 Image showing the abundant extracellular polymeric substance (EPS) secretions (green) surrounding cyanobacteria and heterotrophic bacteria (blue) within a stromatolite microbial mat. The large round objects (red) are calcium carbonate sediments, called ooids. Image was collected using a confocal scanning laser microscopy (CSLM) (scale bar = 10 μm).

or steric-inhibition (i.e., blocking the binding) of these functional groups may allow Ca^{++} ions to accumulate locally reaching saturation levels in hydrated pockets within the EPS. Then, certain functional groups on EPS molecules may serve as a potential nucleation site to form a unidentate binding of a Ca^{++} cation, and allowing the cation to complex with a carbonate anion to initiate precipitation of aragonite (CaCO_3), a process which initiates the biogeomineral formation of calcium carbonate. This interest has been fueled by exciting studies of biologically mediated mineral formation that occurs within early oceans (Arp et al., 2001) and the important role of CaCO_3 in global carbon flux. The secretion of EPS by microbial flora likely developed early in the evolution of life, as evidenced by their roles in stromatolite formation, and broader microbial mat processes. Evidence supporting the presence of EPS in fossil microbial mats and other types of microbial-based fossils are now being found.

The presence of EPS in sediment systems strongly influences the physical stability of the sediments against resuspension by wave action and currents. Different physical forms of EPS, ranging from highly soluble (in water) to cohesive gels, have different (i.e., quantitative) stabilizing effects on sediments (Underwood and Paterson, 2003). Additionally, the presence of EPS contributes to the optical properties (i.e., reflectance, scattering, and absorbance) by sediments.

In open aquatic systems such as oceans, microorganisms often form aggregated communities, also called "marine snow," which occur suspended within the water column. Here, the EPS are especially important in the cohesion of cells and molecules into aggregates. Smaller non-cell containing forms of EPS, called "transparent exopolymer particles" (TEP) may aggregate into larger marine snow (Passow et al., 2001). These aggregation processes become especially pronounced during the later stage of phytoplankton blooms in oceans and lakes, and during extreme examples called "excessive mucilage events," such as those which occur periodically in the northern Adriatic Sea and other areas. Ultimately, the aggregation process eventually sends the microbial cells, EPS, and their sorbed ions and molecules to the sediments. This sedimentation process collectively carries with itself large quantities of carbon and important trace elements, and contributes to the global flux of these elements in oceans.

Conclusion

EPS are extracellular polymeric substances that are produced and secreted by microorganisms, and may vary in their physical state, chemical properties, and functional roles to cells. The EPS are often produced in association with a biofilm. The production of EPS influences many processes that have broader biological and geobiological importance. For example, EPS gels alter the physical stability and optical signatures of sediments and seawater,

and are involved in biogeomineral precipitation, and the global flux of carbon and other elements within oceans. Finally, biofilms and their EPS are prominent components of extreme environments ranging from cold Antarctic epipontic communities to anhydrophilic hypersaline ponds to the high temperatures/pressures of hydrothermal vent systems.

Summary

It is now realized that most bacteria and other microorganisms (e.g., cyanobacteria, Archea, diatoms) exist as attached "biofilms." The biofilm consists of microbial cells that have attached to a surface (or aggregated), and have surrounded themselves within a secreted gelatinous matrix of EPS. EPS is an operational designation that refers to the milieu of relatively "large" molecules contained in the extracellular matrix in proximity to cells. The EPS confer different physical/chemical properties and provides cells with the potential capability to bind and sequester important ions, nutrients, and other molecules, and create strong biogeochemical gradients over small (i.e., micrometer) spatial distances. Together, EPS form the three-dimensional architecture from which cells may structure interactions, and even construct organized macrostructures. A great deal of interest is developing in the role of EPS as it influences the broader area of geobiology. This interest centers on the role of biologically produced molecules in mineral formation.

Definition

The word “extreme” comes from the Latin word “*extremus*,” the superlative of “*exter*” (= on the outside) (Rothschild and Mancinelli, 2001). Whereas there is no general agreement on how to define an extreme environment, the term is commonly used for any setting that exhibits life conditions detrimental or fatal to higher organisms with respect to its physicochemical properties. Thus, extreme environments differ in one or more aspects from those which humans consider as “normal,” moderate conditions with circumneutral pH, temperatures between 20°C and 35°C, pressures around 0.1 MPA (1 atm), and adequate concentrations of nutrient and saline. It should be considered, however, that such definition represents an anthropocentric view and that what is extreme and what is normal from a microbial perspective remains questionable.

If not completely uninhabitable to life, extreme environments typically harbor specially adapted organisms, the so-called **extremophiles**. Most extremophiles are unicellular organisms, that is, protists, bacteria, and archaea. As a rule, extreme environments show a low diversity of multicellular organisms and only few animals are able to withstand the harsh conditions of particular extreme environments. Terms describing extremophiles usually combine an environment-specific prefix with the suffix “-phile” (Greek word for “-loving”). Replacing the suffix “-phile” by “-tolerant” implies that an organism *tolerates* rather than *requires* the respective conditions, and actually has its optimum at more moderate conditions. Prefixes may be combined for organisms that thrive in more than one extreme (e.g., “thermoacidophiles”). Such organisms are termed **polyextremophiles**.

Extreme environments can be categorized into several classes.

Acidic environments

Environments below pH 5, including, for example, sulfuric pools, geysers, and areas polluted by acid mine drainage are called acidic environments. Organisms dependent on acidic conditions below pH 5 (pH 7 = neutral) are called **acidophiles**. Examples are the bacterial genus *Acidithiobacillus* (used in biomining, see entry), *Ferroplasma acidophilum*, a sulfuric-acid producing

archaeon involved in acid mine drainage (see entry *Acid Rock Drainage*), the red alga *Cyanidium caldarium* (the most heat and acid tolerant alga known), the green alga *Dunaliella acidophila*, the fungus *Trichosporon cerebriae*, and the archaeum *Picrophilus* (Rothschild and Mancinelli, 2001). The major challenge for these organisms is to maintain their internal cellular pH at a constant, circumneutral level, that is, around pH 7. Individual strategies encompass, *inter alia*, (i) reinforcement of the cell membrane, (ii) secretion of extracellular polymeric substances (EPS) (see entry “*Extracellular Polymeric Substances (EPS)*”) to limit proton diffusion into the cell, (iii) secretion of buffer molecules capable of sequestering protons, including, for example, basic amino acids (lysine, histidine and arginine), and (iv) the ability to actively pump protons out of the cell (for reviews, see Baker-Austin and Dopson, 2007; Rothschild and Mancinelli, 2001).

Alkaline environments

Environments above pH 9 include, for example, hydrothermal springs (Figure 1a) and soda lakes (e.g., Lake Van, Mono Lake, Figure 1b) are called alkaline environments. Organisms dependent on alkaline (high) pH values > pH 9 are termed **alkaliphiles** (Horikoshi, 1998). Examples are the bacterium *Bacillus alcalophilus* (Horikoshi, 1998) and the archaeon *Natronococcus occultus* (Tindall et al., 1984). Like acidic habitats, alkaline environments pose particular requirements for the inhabiting organisms, specifically the ability to maintain internal pH at a level not higher than ~pH 8.5 (Horikoshi, 1998). Strategies to achieve this include, *inter alia*, (i) buffering cell cytoplasm using polyamines rich in amino acids with positively charged side groups (lysine, arginine, and histidine), (ii) introducing acidic compounds to protect the cell from the alkaline environment (e.g., teichoic acid, acidic amino acids, and uronic acids), (iii) Na⁺-ion channels actively driving the transfer of protons into the cell, (iv) synthesis of specific enzymes resistant to high pH. The enzymes of alkaliphiles found a variety of industrial applications. For instance, alkaline proteases, protein-hydrolyzing enzymes, are widely used in the detergent industry.

Hypersaline environments

Environments with salt concentrations greater than that of seawater (35‰; Figure 1, see also Chapters “*Saline Lakes*”, “*Deep Biosphere of Salt Deposits*”) are called hypersaline environments. Organisms dependent on salt concentrations greater than 35‰ (sea water) are called **halophiles**. Halophiles are known from the Archaea, Bacteria, and Eukarya (Grant et al., 1998; Gunde-Cimerron et al., 2005). Eukaryotes are represented, for instance by the green alga *Dunaliella*, and even animals occur in hypersaline environments, although in low species diversity (e.g., the brine shrimp *Artemia*, and the salt fly *Ephydra*). In the bacterial domain, halophiles represent many different taxonomic groups, whereas

The word “extreme” comes from the Latin word “*extremus*,” the superlative of “*exter*” (= on the outside) (Rothschild and Mancinelli, 2001). Whereas there is no general agreement on how to define an extreme environment, the term is commonly used for any setting that exhibits life conditions detrimental or fatal to higher organisms with respect to its physicochemical properties. Thus, extreme environments differ in one or more aspects from those which humans consider as “normal,” moderate conditions with circumneutral pH, temperatures between 20°C and 35°C, pressures around 0.1 MPA (1 atm), and adequate concentrations of nutrient and saline. It should be considered, however, that such definition represents an anthropocentric view and that what is extreme and what is normal from a microbial perspective remains questionable.

If not completely uninhabitable to life, extreme environments typically harbor specially adapted organisms, the so-called **extremophiles**. Most extremophiles are unicellular organisms, that is, protists, bacteria, and archaea. As a rule, extreme environments show a low diversity of multicellular organisms and only few animals are able to withstand the harsh conditions of particular extreme environments. Terms describing extremophiles usually combine an environment-specific prefix with the suffix “-phile” (Greek word for “-loving”). Replacing the suffix “-phile” by “-tolerant” implies that an organism *tolerates* rather than *requires* the respective conditions, and actually has its optimum at more moderate conditions. Prefixes may be combined for organisms that thrive in more than one extreme (e.g., “thermoacidophiles”). Such organisms are termed **polyextremophiles**.

Extreme environments can be categorized into several classes.

Acidic environments

Environments below pH 5, including, for example, sulfuric pools, geysers, and areas polluted by acid mine drainage are called acidic environments. Organisms dependent on acidic conditions below pH 5 (pH 7 = neutral) are called **acidophiles**. Examples are the bacterial genus *Acidithiobacillus* (used in biomining, see entry), *Ferroplasma acidophilum*, a sulfuric-acid producing

archaeon involved in acid mine drainage (see entry *Acid Rock Drainage*), the red alga *Cyanidium caldarium* (the most heat and acid tolerant alga known), the green alga *Dunaliella acidophila*, the fungus *Trichosporon cerebriae*, and the archaeum *Picrophilus* (Rothschild and Mancinelli, 2001). The major challenge for these organisms is to maintain their internal cellular pH at a constant, circumneutral level, that is, around pH 7. Individual strategies encompass, *inter alia*, (i) reinforcement of the cell membrane, (ii) secretion of extracellular polymeric substances (EPS) (see entry “*Extracellular Polymeric Substances (EPS)*”) to limit proton diffusion into the cell, (iii) secretion of buffer molecules capable of sequestering protons, including, for example, basic amino acids (lysine, histidine and arginine), and (iv) the ability to actively pump protons out of the cell (for reviews, see Baker-Austin and Dopson, 2007; Rothschild and Mancinelli, 2001).

Alkaline environments

Environments above pH 9 include, for example, hydrothermal springs (Figure 1a) and soda lakes (e.g., Lake Van, Mono Lake, Figure 1b) are called alkaline environments. Organisms dependent on alkaline (high) pH values > pH 9 are termed **alkaliphiles** (Horikoshi, 1998). Examples are the bacterium *Bacillus alcalophilus* (Horikoshi, 1998) and the archaeon *Natronococcus occultus* (Tindall et al., 1984). Like acidic habitats, alkaline environments pose particular requirements for the inhabiting organisms, specifically the ability to maintain internal pH at a level not higher than ~pH 8.5 (Horikoshi, 1998). Strategies to achieve this include, *inter alia*, (i) buffering cell cytoplasm using polyamines rich in amino acids with positively charged side groups (lysine, arginine, and histidine), (ii) introducing acidic compounds to protect the cell from the alkaline environment (e.g., teichoic acid, acidic amino acids, and uronic acids), (iii) Na⁺-ion channels actively driving the transfer of protons into the cell, (iv) synthesis of specific enzymes resistant to high pH. The enzymes of alkaliphiles found a variety of industrial applications. For instance, alkaline proteases, protein-hydrolyzing enzymes, are widely used in the detergent industry.

Hypersaline environments

Environments with salt concentrations greater than that of seawater (35‰; Figure 1, see also Chapters “*Saline Lakes*”, “*Deep Biosphere of Salt Deposits*”) are called hypersaline environments. Organisms dependent on salt concentrations greater than 35‰ (sea water) are called **halophiles**. Halophiles are known from the Archaea, Bacteria, and Eukarya (Grant et al., 1998; Gunde-Cimerron et al., 2005). Eukaryotes are represented, for instance by the green alga *Dunaliella*, and even animals occur in hypersaline environments, although in low species diversity (e.g., the brine shrimp *Artemia*, and the salt fly *Ephydra*). In the bacterial domain, halophiles represent many different taxonomic groups, whereas

Extreme Environments, Figure 1 Examples and features of extreme environments. (Images courtesy of J. Reitner and G. Arp) (a) A volcanic hot spring on Iceland, providing an environment for thermophilic bacteria and archaea. The spring bottom shows a temperature zonation of brown and black microbial mats. (b) Mono Lake, California, is an excellent example for both a hypersaline and an alkaline environment. Being a terminal lake, Mono Lake has no outlet to the ocean, and dissolved salts in the runoff have increased the water's alkalinity ($\text{pH} \sim 10$) and salt concentration (70‰). (c) Underwater view of the ~ 2 m deep hypersaline Lake 21 on Christmas Island (Republic of Kiribati). Kiritimati is a raised atoll, with a rather arid climate. Periodically flooding with sea water and subsequent evaporation cause the salinity of numerous inland lakes to increase to values about 120‰, four times that of sea water. The lake bottom is covered with microbial mats dominated by Cyanobacteria at the surface. (d) A calcifying microbial mat from the same setting as in (c), showing a complex layering of differently pigmented microbes. In the deeper parts of the mat, carbonate precipitation proceeds under anaerobic conditions, ultimately producing massive microbialites. (e) The Bonneville Salt Flats in northwestern Utah, USA, are a remnant of the ancient glacial Lake Bonneville. Up to 1.8 m, thick salt crusts provide an extremely hypertonic environment for halo- and xerophilic microorganisms. (f) Lake Clifton, 120 km south of Perth (Western Australia), provides a fragile ecosystem where the growth of a large thrombolite reef (see "Microbialites") is sustained by calcium carbonate rich aquifers water and strong seasonal trends in salinity (salinity 30–80 ‰). Notably, these modern thrombolitic microbialites coexist with a diverse invertebrate fauna.

those in the archaeal domain fell into a single order (*Halobacteriales*) and family (*Halobacteriaceae*; DasSarma and DasSarma, 2008). The most significant challenge for halophiles is to prevent the loss of water from the cell into the saline environment, and the accumulation of excess salt concentrations within the cell. The latter may give rise to the collapse of proteins and macromolecules, because the electric charges of the salt ions disturb the electrostatic interactions within biomacromolecules. Halophiles basically use two strategies to tackle these challenges. (i) Halophilic bacteria and algae accumulate organic compatible solutes, polar, highly soluble molecules uncharged at physiological pH, such as amino acids and their derivatives to counterbalance the osmotic pressure of the surrounding medium (Galinski, 1993; Oren, 1999). (ii) Halophilic archaea, thriving at NaCl concentrations higher than 1.5 M, use the so-called “salt-in strategy.” These most halophilic organisms concentrate K^+ ions within the cell in order to balance osmotic pressure. Their proteins are particularly rich in acidic amino acids, thus enhancing resistance against structural collapse. For more information, see entry “*Halobacteria – Halophiles*.” Several reports provided evidence that viable extremely halophilic microorganisms were enclosed in ancient salt sediments. Please refer to “*Deep Biosphere of Salt Deposits*” for details.

Extremely hot environments

Environments periodically or consistently above 40°C are called extremely hot environments (Stetter, 1998). Depending on the temperature, these settings harbor **thermophiles** (growth optimum 45–80°C, Martinko and Madigan, 2006) or **hyperthermophiles** (growth optimum above 80°C). (Organisms dependent on moderate temperatures between 10°C and 50°C (optimum 30–40°C) are called **mesophiles**.) Whereas thermophiles have a fairly broad ecological amplitude, including, for example, hot waters, sun-heated soils, and waste dumps, hyperthermophiles mostly occur at water-containing, geothermally heated terrestrial and marine springs and sediments (Figure 1a). As a rule, prokaryotes are able to grow at higher temperatures than eukaryotes (limit ~65°C). Accordingly, hyperthermophilic life is mainly represented by deeply branching bacteria, (e.g., *Aquifex*, *Thermotoga*) and archaea (e.g., *Sulfolobus*, *Methanothermus*; Stetter, 1998). The highest commonly accepted temperature for life has been reported for the hyperthermopiezophilic archaeon *Methanopyrus kandleri* (122°C; Takai et al., 2008). The challenge for organisms living in hot environments lies in avoiding thermal degradation of cellular biomacromolecules, which may, for example, result in unfolding of proteins. Individual strategies encompass stabilization of proteins by introducing additional disulfide bridges, ionic interactions, hydrogen bonds, and hydrophobic interactions. Another alternative is to introduce the proline residue at particular sites into proteins (the

proline rule; Imanaka, 2008). Because many scientists believe that prebiotic molecules and the first living organisms originated in hot environments, hyperthermophiles may provide insight into the early stages of life on Earth. Please refer to “*Hydrothermal Environments, Terrestrial*,” “*Hydrothermal Environments, Marine*,” “*Hot Springs and Geysers*,” and “*Origin of Life*” for further reading.

High-pressure environments

Environments under extreme hydrostatic or petrostatic (rock) pressure are high-pressure environments. Organisms thriving in these settings are called **piezophiles** (formerly barophiles). Broadly spoken, **piezophiles** organisms dependent on pressures greater than atmospheric pressure (0.1 MPa, Yayanos, 1998), although organisms living, for example, in shallow coastal waters are commonly neither considered as piezophiles nor as extremophiles. Based on their optimal growth pressure, piezophiles have further been classified as piezotolerant (0.1–10 MPa; 10 MPa $\approx$ 1,000 m water depth), piezophilic (10–50 MPa), and hyperpiezophilic (>50 MPa) bacteria and archaea (Fang and Bazylinski, 2008). Whereas, as a rule, the relative growth rate of these organisms decreases with pressure, the upper pressure limit of life has not yet been determined (Yayanos, 1998; Schrenk et al., 2010). High pressures affect biological systems by making the structures (e.g., membranes) more compact, as opposed to the effects of high temperature. Pressurization hinders any process resulting in a positive volume change, and vice versa. For example, if a reaction is accompanied by a volume decrease of 300 mL mol⁻¹, it is enhanced more than 200,000-fold by applying a pressure of 100 MPa ($\approx$ 10,000 m water depth; Abe et al., 1999). Likewise, hydrostatic pressure has been shown to exert a considerable influence on many protein–protein interactions, the efficacy of enzymatic catalysis, replication, and translation. Piezophiles have therefore evolved specific adaptations, for example, in terms of membrane lipid composition and cell division. Pressure has also a significant effect on microbial-mediated redox reactions, and metabolic versatility appears to be a specific adaptation to deep environments (Fang and Bazylinski, 2008; Lauro and Bartlett, 2008). For detailed reading, please refer to entry “*Piezophilic Bacteria*.”

Extremely cold environments

Environments with temperatures below 5°C for prolonged periods of time, such as cold polar regions, glaciers, sea-ice, deep-sea sediments, and permafrost soils are considered extremely cold environments. Organisms capable of growth and reproduction in these settings are called **psychrophiles** (cryophiles). They depend on low temperatures (< 0°C to 20°C) and have a growth optimum below 15°C (Morita, 1975). The lowest temperature limit for life seems to be around –20°C and has been reported for bacteria living in permafrost soil and in sea-ice (D’Amico

et al., 2006). Psychrophiles are found in all three domains of life. Eukaryotes such as *algae* (e.g., sea-ice diatoms, the “snow alga” *Chlamydomonas nivalis*), protozoans, fungi, and even small metazoans frequently occur, but psychrophiles are most abundant among diverse lineages within the bacteria (e.g., *Pseudomonas* spp., *Vibrio* spp., several cyanobacterial genera) and, less often cited, archaea (e.g., *Methanogenium* and *Methanococcus*) (Garrison, 1991; D’Amico et al., 2006). Main cold-induced challenges posed to psychrophiles within their habitats encompass (i) reduced enzyme activity, (ii) decreased membrane fluidity, (iii) altered transport of nutrients and waste products, (iv) decreased rates of transcription, translation, and cell division, (v) protein cold-denaturation and inappropriate protein folding, (viii) intracellular ice formation, and (ix) low water availability (see D’Amico et al., 2006, for a review). Psychrophilic organisms have successfully evolved strategies to overcome these negative effects of low temperatures. Such strategies involve modifications of the cell membrane composition toward a higher content of unsaturated, branched, or short-chain fatty acids, and large polar head groups (Chintalapati et al., 2004). Psychrophiles also synthesize specific antifreeze proteins, trehalose, and extracellular polymeric substances (EPS), which play an important role as cryoprotectants to keep the intercellular space liquid and protect the DNA at temperatures below water’s freezing point (see D’Amico et al., 2006, for a review). For further reading, please refer to “*Permafrost Microbiology*.”

Extremely dry environments

Environments without free water are considered extremely dry environments and they include hot and cold deserts, and some terrestrial endolithic habitats (see also Chapter “*Endoliths*”). Organisms dependent on very dry environments are termed **xerophiles**, whereas those tolerating only temporary desiccation are referred to as “xerotolerant.” Most organisms thriving in very dry environments are actually xerotolerants, which rely on at least periodically available free water. A strategy to cope with prolonged periods of dryness is to enter the state of anhydrobiosis, which is characterized by little intracellular water and no metabolic activity. Organisms that can become anhydrobiotic are found among bacteria, yeast, fungi, plants, and even animals such as nematodes and the brine shrimp *Artemia salina* (Rothschild and Mancinelli, 2001). The terms “xerophile” and “xerotolerant” are often used to include organisms thriving under conditions of low water activity $a_w < 0.80$. The a_w is a measure of the amount of water within a medium that an organism can use to support growth. It represents the ratio of the water vapor pressure of the substrate to that of pure water under the same conditions and is expressed as a fraction (pure water, $a_w = 1$; saturated NaCl, $a_w = 0.75$). The lowest a_w value recorded for growth to date was reported for the spoilage mould *Xeromyces bisporus* ($a_w = 0.61$; see Grant, 2004 for a review). According to this

definition, the most xerophilic organisms known, thrive in foods preserved by some form of dehydration or enhanced sugar levels, and in hypersaline environments where water availability is limited by a high concentration of salts (Grant, 2004). Whereas the former are dominated by xerophilic filamentous fungi and yeasts, high-salt environments are almost exclusively populated by prokaryotes. For the strategies employed by these organisms to cope with the osmotic stress exerted by these environments see above, and entry “*Halobacteria – Halophiles*.”

High-radiation environments

Environments exposed to high doses of ionizing radiation are high-radiation environments. Ionizing radiation is radiation with sufficient energy to ionize molecules, most commonly ultraviolet (UV) radiation and natural radioactivity. When such radiation passes through (living) matter, ions and free radicals are produced that react rapidly and modify molecules (Cox and Battista, 2005). Ionizing radiation is therefore potentially detrimental for life, mainly due to DNA damage resulting from the generation of reactive oxygen species and the hydrolytic cleavage of water. Organisms that are capable of withstanding high doses of ionizing radiation are called **radioresistant**. There is no clear pattern of evolution among ionizing-radiation-resistant species, and they occur scattered over the three domains of life. Well-studied microbial examples are the archaeon *Thermococcus gammatolerans* (Jolivet et al., 2003) and the bacterium *Deinococcus radiodurans* (Cox and Battista, 2005). Strategies to adapt to high doses of ionizing radiation involve (i) increasing the numbers of genome copies, (ii) tight spatial arrangement of nucleoids, (iii) accumulation of efficient radical scavengers, (iv) delaying DNA replication until damage repair has been completed, and (v) improved enzymatic genome-repair process. For further reading, please refer to entry “*Radioactivity*.”

Summary

“*Extreme environment*” refers to any setting that exhibits life conditions detrimental or fatal to higher organisms with respect to its physicochemical properties, in particular pH, temperature, pressure, saline concentrations, and radiation. Major classes of extreme environments encompass acidic ($\text{pH} < 5$), alkaline ($\text{pH} > 9$), hypersaline (salinity $> 35\%$), pressurized ($> 0.1 \text{ MPa}$), hot ($> 40^\circ\text{C}$), cold ($< 5^\circ\text{C}$), dry ($a_w < 0.80$), and high-radiation environments. These environments typically harbor specially adapted organisms, the so-called extremophiles. These can be classified into acidophiles, alkaliphiles, (hyper-) thermophiles, psychrophiles, xerophiles, and radioresistant organisms.

Definition

Fe(II)-oxidizing prokaryotes. Diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to oxidize Fe(II), ferrous iron, to Fe(III), ferric iron. The electrons obtained from the oxidation of Fe(II) are utilized for energy generation in aerobic or anaerobic respiration and/or for assimilative reduction reactions.

Introduction

Aerobic neutrophilic Fe(II)-oxidizing bacteria were among the first environmentally relevant prokaryotes that were discovered and studied in the nineteenth century. At that time, eye-catching ochre deposits in ponds and slowly running waters had attracted the attention of microbiologists. Microscopic analyses of such ochre deposits revealed the prevalence of twisted stalks and/or sheaths that were covered with iron minerals. Bacteria were suggested to be responsible for the production of these specific iron-covered structures, and subsequently the first aerobic Fe(II)-oxidizing prokaryotes were described: *Gallionella ferruginea* and *Leptothrix ochracea* (reviewed by Emerson, 2000; Canfield et al., 2005). In contrast, the anaerobic oxidation of Fe(II) by phototrophic bacteria (Widdel et al., 1993), nitrate-reducing bacteria

(Straub et al., 1996), and archaea (Hafenbradl et al., 1996) was not discovered until the end of the twentieth century. Aerobic and anaerobic Fe(II)-oxidizing prokaryotes play decisive roles in the biogeochemical cycle of iron. In comparison to other physiological groups, only few species of Fe(II)-oxidizing prokaryotes are available in pure culture. The capability to oxidize Fe(II) is apparently phylogenetically widespread because the known species belong to diverse phyla of the *Bacteria* and the *Archaea*. The mechanism(s) of prokaryotic Fe(II)-oxidation are largely unknown (Canfield et al., 2005).

Geochemical aspects of Fe(II)

Iron is the fourth most abundant element in the Earth's crust, and depending upon the geochemical conditions, it occurs either in soluble forms or in a variety of minerals (Cornell and Schwertmann, 2003). In natural habitats, Fe(III) minerals are reduced to Fe(II) mainly by the metabolic activities of prokaryotes. The concentration of dissolved Fe(II) is controlled by precipitation-dissolution reactions and by adsorption processes: Fe(II) precipitates with carbonates, phosphates, or sulfides and tends to adsorb to soil particles and mineral surfaces (Cornell and Schwertmann, 2003; Canfield et al., 2005). Chemical reoxidation reactions of Fe(II) depend on the pH and on the presence of appropriate oxidants. The reaction rate of Fe(II) with molecular oxygen is very low at acidic pH values, and hence Fe(II) is fairly stable in the presence of oxygen under acidic conditions. With increasing pH, the reaction rate of Fe(II) and molecular oxygen increases, and at fully aerated conditions Fe(II) is rapidly oxidized to ferric iron (Emerson, 2000; Canfield et al., 2005). In the absence of molecular oxygen, Fe(II) can be chemically oxidized at appreciable rates only by nitrite or Mn(IV). However, Mn(IV) minerals are insoluble, and the environmental significance of these nondiffusible oxidants is therefore limited (Canfield et al., 2005). It is thus

speculated that anaerobic Fe(II)-oxidizing prokaryotes are important catalysts for the reoxidation of Fe(II) in anoxic environments.

Fe(II) as electron donor in aerobic or anaerobic respiration

Dissimilatory Fe(II)-oxidizing prokaryotes utilize Fe(II) as electron donor in aerobic or anaerobic respiration, i.e., they gain energy by coupling the oxidation of Fe(II) to the reduction of molecular oxygen or to the reduction of nitrate. As in the oxidation of Fe(II) to Fe(III), only one electron can be obtained, dissimilatory Fe(II)-oxidizing prokaryotes have to oxidize large quantities of Fe(II) to gain enough energy for maintenance and growth. Today, three physiological groups of prokaryotes are known to grow with Fe(II) as electron donor: acidophilic aerobic, neutrophilic aerobic, and neutrophilic nitrate-reducing prokaryotes. Due to energetic considerations, the oxidation of Fe(II) with nitrate at low pH values should also yield enough energy for prokaryotic growth. However, acidophilic Fe(II)-oxidation coupled to the reduction of nitrate has not been reported so far (Kappler and Straub, 2005; Appelo and Postma, 2007). The dissimilative oxidation of Fe(II) leads to the formation of Fe(III) minerals which are well soluble under acidic conditions but barely soluble at neutral pH. Hence, neutrophilic Fe(II)-oxidizing prokaryotes have to cope with a virtually insoluble metabolic end product.

Acidophilic aerobic Fe(II)-oxidizing prokaryotes

A variety of autotrophic and heterotrophic prokaryotes that thrive in environments of low pH (< 3) were described to grow by dissimilatory aerobic oxidation of ferrous iron (Johnson, 2007). At acidic pH values, Fe(II) is stable in the presence of molecular oxygen, and hence prokaryotes do not need to compete with the chemical oxidation. However, the energy gain of acidophilic aerobic Fe(II) oxidation is low because the redox potential of the redox pair $\text{Fe}^{3+}/\text{Fe}^{2+}$ is with +770 mV rather high. The difference to the redox potential of the redox pair $\text{O}_2/\text{H}_2\text{O}$ (> +1,000 mV below pH 3) allows therefore only little energy generation (Kappler and Straub, 2005; Appelo and Postma, 2007). Nevertheless, representatives of different phyla of the *Bacteria* (e.g., *Acidithiobacillus ferrooxidans*, *Sulfobacillus acidophilus*) and the *Archaea* (*Acidianus brierleyi*, *Sulfolobus metallicus*) exploit Fe(II) in aerobic respiration. Moreover, three species of the genus *Leptospirillum* are obligate aerobic Fe(II)-oxidizing bacteria, i.e., Fe(II) is the only electron donor and molecular oxygen the only electron acceptor utilized (Johnson, 2007). All other acidophilic Fe(II)-oxidizing prokaryotes make use of alternative electron donors (e.g., hydrogen, sulfur) and sulfur or Fe(III) as alternative electron acceptors. Species of acidophilic Fe(II)-oxidizing bacteria that also grow by dissimilatory reduction of Fe(III) were shown to catalyze the cycling of iron in laboratory experiments (Johnson et al., 1993).

Acidithiobacillus ferrooxidans was the first acidophilic aerobic Fe(II)-oxidizing bacterium that was isolated (Temple and Colmer, 1951); it belongs to the *Gammaproteobacteria* and is so far the best studied of all acidophilic prokaryotes. However, details of the flow of electrons from Fe(II) to molecular oxygen are still debated. Apparently, Fe(II) is oxidized on the cell surface at the outer membrane. Subsequently, a variety of membrane-bound and periplasmic cytochromes plus the periplasmic copper protein rusticyanin transfer the electrons to a cytochrome *c* oxidase. There the electrons are used together with protons to reduce molecular oxygen to water (Johnson, 2007; Castelle et al., 2008).

Neutrophilic aerobic Fe(II)-oxidizing bacteria

So far, only few representatives of the *Alpha*-, *Beta*-, and *Gammaproteobacteria* are described to grow by dissimilatory aerobic oxidation of Fe(II) at neutral pH. This physiological group gains more energy than their acidophilic counterparts because the difference between the redox potentials of the relevant redox couples is greater at neutral than at acidic pH values ($\text{Fe(III)/Fe(II)} < +100$ mV; $\text{O}_2/\text{H}_2\text{O} +820$ mV; Kappler and Straub, 2005; Appelo and Postma, 2007). However, in oxic environments of neutral pH Fe(II) has a half-life in the order of few minutes and is chemically oxidized to ferric iron (Canfield et al., 2005). This competition with the chemical oxidation is likely the major reason why neutrophilic aerobic Fe(II)-oxidizing bacteria thrive preferentially in microoxic niches or oxic/anoxic boundaries. Laboratory studies showed that the activity of Fe(II)-oxidizing bacteria contributes up to 90% to the formation of Fe(III) under such conditions. Typical habitats for neutrophilic aerobic Fe(II)-oxidizing bacteria include groundwater springs, freshwater, and marine hydrothermal vents, wetlands, and plant rhizospheres (Emerson, 2000). Due to their production of conspicuous iron-encrusted twisted stalks or sheaths, *Gallionella ferruginea* and *Leptothrix ochracea* were the first Fe(II)-oxidizing bacteria that were already discovered in the nineteenth century. Only during the past few years, additional morphologically inconspicuous aerobic Fe(II)-oxidizing bacteria were isolated, e.g., *Ferritrophicum radicola* and *Sideroxydans paludicola* (Canfield et al., 2005; Weiss et al., 2007). According to physiological studies, several of the novel strains are obligate aerobic Fe(II)-oxidizing bacteria, i.e., Fe(II) is the only electron donor and molecular oxygen the only electron acceptor utilized (Weiss et al., 2007).

Neutrophilic anaerobic Fe(II)-oxidizing nitrate-reducing prokaryotes

Under anoxic conditions, bacteria (*Alpha*-, *Beta*-, *Gamma*- and *Deltaproteobacteria*) and archaea (*Archaeoglobales*) are capable of oxidizing Fe(II) with nitrate as the terminal electron acceptor. At pH 7, all redox pairs of the nitrate reduction pathway can accept electrons from Fe(II), because their redox potentials are more positive than that

of the iron redox couple (Straub et al., 1996). Nitrate-dependent Fe(II) oxidation was reported for diverse habitats such as rice paddy soil, activated sewage sludge, freshwater or marine sediments (Canfield et al., 2005). The first observation of this metabolism was made with a freshwater enrichment culture: Fe(II) was oxidized to Fe(III) and nitrate was concomitantly and stoichiometrically reduced to molecular nitrogen (Straub et al., 1996). As Fe(II) was the sole electron donor supplied, Fe(II) oxidation coupled to nitrate reduction definitely supported cell growth in this enrichment culture. The situation is not so clear in most pure cultures of Fe(II)-oxidizing nitrate-reducing bacteria (e.g., *Acidovorax* sp. strain BoFeN1 or *Thermomonas* sp. strain BrG3) because they need an organic co-substrate for growth. In such strains it is questioned whether Fe(II) oxidation is beneficial and supports cell growth or whether Fe(II) is just oxidized in a rather unspecific side reaction. All known species are able to utilize alternative electron donors (e.g., hydrogen, organic acids) and alternative electron acceptors (nitrite, oxygen, ferric iron). *Geobacter metallireducens*, isolated as Fe(III)-reducing bacterium, couples the oxidation of Fe(II) to the reduction of nitrate to ammonium; it is unclear if *G. metallireducens* obtains energy by this process (Lovley et al., 2004; Canfield et al., 2005). *Ferroglobus placidus* is so far the only representative of the domain *Archaea* that grows by coupling the dissimilatory oxidation of Fe(II) to the reduction of nitrate to nitric oxide and nitrogen dioxide. Alternatively, *F. placidus* utilizes hydrogen, sulfide, acetate, or monoaromatic compounds as electron donor and thiosulfate or Fe(III) as electron acceptor (Hafenbradl et al., 1996; Lovley et al., 2004).

Fe(II) as electron donor for assimilative reduction reactions

Various groups of prokaryotes are able to reduce oxidized inorganic compounds for the synthesis of biomass. Such assimilative reduction reactions require a source of electrons (Canfield et al., 2005). Phylogenetically and physiologically different groups of chemotrophic and phototrophic prokaryotes have the ability to exploit Fe(II) as source of electrons for assimilative reduction reactions such as the fixation of carbon dioxide. Chemotrophic acidophilic and neutrophilic, aerobic and anaerobic Fe(II)-oxidizing prokaryotes have been discussed before because they oxidize the major fraction of Fe(II) during respiratory energy generation. In contrast, phototrophic Fe(II)-oxidizing prokaryotes utilize light as energy source and oxidize Fe(II) exclusively for assimilative purposes. The assimilative oxidation of Fe(II) leads to the formation of Fe(III) which is barely soluble at neutral pH. Neutrophilic phototrophic Fe(II)-oxidizing bacteria therefore have to cope with a virtually insoluble metabolic end product.

Anaerobic phototrophic Fe(II) oxidation

Anoxygenic phototrophic bacteria were the first prokaryotes discovered that oxidize Fe(II) in the absence of

molecular oxygen (Widdel et al., 1993). So far, only few cultures of Fe(II)-oxidizing anoxygenic phototrophic bacteria were established either from freshwater or from marine sediments. They are affiliated with the purple sulfur (*Thiodictyon* sp. strain F4), the purple non-sulfur (e.g., *Rhodobacter* sp. strain SW2, *Rhodovulum robiginosum*), or the green sulfur bacteria (*Chlorobium ferrooxidans*). All strains have the ability to utilize alternative electron donors such as hydrogen, reduced sulfur compounds, or organic acids (Canfield et al., 2005). The discovery of anoxygenic phototrophic bacteria that directly catalyze the oxidation of Fe(II), provides an alternative or additional explanation for the origin of Precambrian banded iron formations (Widdel et al., 1993; Kappler and Straub, 2005).

Summary

Phylogenetically diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to oxidize Fe(II) during aerobic or anaerobic respiration and/or for assimilative reduction reactions. Only one electron can be obtained from the oxidation of Fe(II) to Fe(III) and Fe(II)-oxidizing prokaryotes have to oxidize large quantities of Fe(II) to sustain cell metabolism. Due to the complex geochemistry of iron, acidophilic and neutrophilic Fe(II)-oxidizing prokaryotes have to cope with different constraints: (1) Acidophilic Fe(II)-oxidizing prokaryotes gain less energy in respiration than their neutrophilic counterparts; (2) Neutrophilic Fe(II)-oxidizing prokaryotes have to cope with a virtually insoluble metabolic end product. It is discussed that anoxygenic phototrophic Fe(II)-oxidizing bacteria contributed to the generation of Precambrian banded iron formations.

Definition

Fe(III)-reducing prokaryotes. Various species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to reduce Fe(III), ferric iron, to Fe(II), ferrous iron, by the transfer of electrons. The electrons for Fe(III) reduction derive mainly from the metabolic oxidation of organic compounds or hydrogen.

Introduction

Reduction of Fe(III) by prokaryotes has been known since the beginning of the twentieth century but was not considered to be of importance. At that time, only few bacterial strains were known to reduce small amounts of Fe(III) during fermentation. In addition, it was misleadingly presumed that prokaryotes cause reduction of Fe(III) mainly indirectly by producing sulfide, releasing organic compounds, lowering the redox potential, or decreasing the pH. This perspective changed notably with the discovery of dissimilatory Fe(III)-reducing bacteria, i.e., bacteria that utilize Fe(III) as terminal electron acceptor in an anaerobic type of respiration (Balashova and Zavarzin, 1979, 1980; Lovley and Phillips, 1988; Myers and Nealson, 1988). In order to gain energy for maintenance and growth by this type of respiration, significant amounts of ferric iron have to be reduced. Additionally, it became clear that neither lowering the redox potential nor decreasing the pH is sufficient to cause Fe(III) reduction. Furthermore, it was demonstrated that only very few organic compounds (e.g., fructose, cysteine) were able to reduce Fe(III) chemically at significant rates. In the last 20 years, numerous dissimilatory Fe(III)-reducing prokaryotes were identified and it is now generally accepted that this physiological group of prokaryotes has a strong influence on the iron geochemistry of most environments. Because many Fe(III)-reducing prokaryotes also have the ability to catalyze the reduction of Mn(IV) or Mn(III) to Mn(II) they additionally influence the geochemistry of manganese (Lovley et al., 2004; Canfield et al., 2005; Kappler and Straub, 2005).

Evolutionary consideration

The ability to reduce Fe(III) occurs widely within the domains *Bacteria* and *Archaea*. Most known Fe(III)-reducing prokaryotes that grow by Fe(III) reduction belong to the phylum Proteobacteria with representatives in each of the five subdivisions *Alpha*- (e.g., *Acidiphilium rubrum*), *Beta*- (e.g., *Ferribacterium limneticum*), *Gamma*- (e.g., *Shewanella oneidensis*), *Delta*- (e.g., *Geobacter sulfurreducens*), and *Epsilonproteobacteria* (e.g., *Sulfurospirillum barnesii*). Several Gram-positive bacteria that belong to the phylum Firmicutes (e.g., *Thermoanaerobacter siderophilus*) and some separate bacterial lineages like *Geothrix fermentans* or *Geovibrio ferrireducens* also have the ability to reduce ferric iron (Lovley et al., 2004). Fe(III) reduction in the domain *Archaea* was discovered by testing pure cultures that had originally not been isolated with Fe(III): Representatives of the phyla Euryarchaeota (e.g., *Pyrococcus furiosus*) and Crenarchaeota (e.g., *Pyrobaculum islandicum*) showed reduction of ferric iron (Vargas et al., 1998). The great phylogenetic diversity of Fe(III)-reducing prokaryotes with representatives in all deeply branching phyla, along with iron isotope studies, supports the hypothesis that Fe(III) reduction was an early mode of energy metabolism. Most known Fe(III)-reducing prokaryotes that grow by Fe(III) reduction belong to the phylum Proteobacteria with representatives in each of the five subdivisions *Alpha*- (e.g., *Acidiphilium rubrum*), *Beta*- (e.g., *Ferribacterium limneticum*), *Gamma*- (e.g., *Shewanella oneidensis*), *Delta*- (e.g., *Geobacter sulfurreducens*), and *Epsilonproteobacteria* (e.g., *Sulfurospirillum barnesii*). Several Gram-positive bacteria that belong to the phylum Firmicutes (e.g., *Thermoanaerobacter siderophilus*) and some separate bacterial lineages like *Geothrix fermentans* or *Geovibrio ferrireducens* also have the ability to reduce ferric iron (Lovley et al., 2004). Fe(III) reduction in the domain *Archaea* was discovered by testing pure cultures that had originally not been isolated with Fe(III): Representatives of the phyla Euryarchaeota (e.g., *Pyrococcus furiosus*) and Crenarchaeota (e.g., *Pyrobaculum islandicum*) showed reduction of ferric iron (Vargas et al., 1998). The great phylogenetic diversity of Fe(III)-reducing prokaryotes with representatives in all deeply branching phyla, along with iron isotope studies, supports the hypothesis that Fe(III) reduction was an early mode of energy metabolism. Further geochemical evidences

suggest that other major electron acceptors such as sulfate, nitrate, or molecular oxygen were not available on early Earth (Lovley et al., 2004; Canfield et al., 2005; Johnson et al., 2008).

Geochemical aspects of Fe(III)

Iron is the fourth most abundant element in the Earth's crust and Fe(III) minerals may account for a few percent dry weight of rocks, soils, and sediments. Hence, in most anoxic ecosystems Fe(III) minerals are the dominant electron acceptors for bacteria and archaea. Today, 16 different Fe(III) oxides, hydroxides, or oxide hydroxides are known and for simplicity they are often collectively termed Fe(III) oxides. They are all composed of Fe together with O and/or OH and differ in composition and crystal structure. Widespread Fe(III) oxides include ferrihydrite, goethite, hematite, lepidocrocite, and magnetite (Cornell and Schwertmann, 2003). In contrast to other electron acceptors such as oxygen, nitrate, or sulfate, Fe(III) oxides are poorly soluble at neutral pH. The solubility of Fe(III) oxides at neutral pH depends furthermore on the type of oxide, the degree of crystallinity and the crystal size, and may range from 10^{-9} M (e.g., ferrihydrite, low crystallinity, small crystals) to 10^{-18} M (e.g., goethite, high crystallinity, large crystals). At circumneutral pH, Fe(III)-reducing prokaryotes therefore have to cope with a virtually insoluble electron acceptor. With increasing acidity, the solubility of Fe(III) oxides increases and ferric iron is well soluble at pH values below 2.5 (Cornell and Schwertmann, 2003). Concomitant with the change in pH and Fe(III) oxide solubility, the redox potential of the transition between ferric and ferrous iron changes significantly. The redox potential of the redox pair $\text{Fe}^{3+}/\text{Fe}^{2+}$ is +770 mV only at acidic pH values. At neutral pH, with poorly crystalline Fe(III) oxides (ferrihydrite, lepidocrocite) as the oxidant, the redox potential ranges between +100 and -100 mV, while the redox potential of more crystalline Fe(III) oxides (goethite, hematite, magnetite) may be as low as -300 mV (Canfield et al., 2005; Straub et al., 2001). In respect of solubility and energetics, acidophilic and neutrophilic Fe(III)-reducing prokaryotes cope with entirely different substrates.

Reduction of Fe(III) by fermenting bacteria

The first Fe(III)-reducing prokaryotes that were studied in laboratory cultures belonged to the domain *Bacteria* and reduced only small amounts of Fe(III) during fermentative growth on organic substrates such as glucose or malate. This physiological group comprises of a variety of bacteria and includes anaerobes (e.g., *Clostridium pasteurianum*, *Vibrio* spp.), facultative anaerobes (e.g., *Escherichia coli*, *Paenibacillus polymyxa*), and aerotolerants (e.g., *Lactobacillus lactis*, *Lactococcus lactis*). Accordingly, Fe(III) reduction by fermenting bacteria was observed under both anoxic and oxic culture conditions. For fermenting bacteria, Fe(III) reduction is

only a minor pathway for electron disposal and research on this type of metabolism fell behind efforts to understand dissimilatory Fe(III) reduction. The mechanism(s) of electron transfer to Fe(III) during fermentation is unknown and it is also unclear whether this process yields energy for growth. Thermodynamic calculations suggest that Fe(III) reduction during fermentation results in a slightly greater energy yield than fermentation alone but experimental evidences are ambiguous (Lovley, 1991; Canfield et al., 2005). So far no representative of the domain *Archaea* was described to reduce Fe(III) during fermentative growth.

Dissimilatory Fe(III)-reducing prokaryotes

Dissimilatory Fe(III)-reducing prokaryotes utilize Fe(III) as terminal electron acceptor in anaerobic respiration, i.e., they gain energy by coupling the oxidation of an electron donor to the reduction of Fe(III). As in the reduction of Fe(III) to Fe(II) only one electron can be disposed, dissimilatory Fe(III)-reducing prokaryotes have to reduce large quantities of Fe(III) to gain enough energy for maintenance and growth. Numerous strains of phylogenetically dispersed, dissimilatory Fe(III)-reducing prokaryotes have been isolated into pure culture or have been detected by molecular techniques in a wide range of pristine or contaminated habitats, including freshwater and marine sediments, wetlands, soils, aquifers, the deep subsurface, deep subterranean thermal water, hydrothermal vents, and hot springs (Lovley et al., 2004). This widespread occurrence correlates well with the ubiquitous presence of Fe(III) minerals. Consistent with the great variety of ecosystems inhabited, pure cultures of Fe(III)-reducing prokaryotes show a wealth of physiological qualities in respect to oxygen concentration (strict or facultative anaerobes), temperature (growth reported between 4 and 121°C), pH (growth reported between pH 1 and 9), and salinity (freshwater and marine species). In addition, autotrophic growth with carbon dioxide as sole carbon source and fixation of molecular nitrogen was described for some species of Fe(III)-reducing prokaryotes. No prokaryote characterized so far, depends solely on Fe(III) as terminal electron acceptor for growth. In the absence of Fe(III), prokaryotes either grow by fermentation (e.g., *Thermotoga maritima*) or utilize alternative electron acceptors. Common alternative electron acceptors include oxygen (e.g., *Pantoea agglomerans*), nitrate (e.g., *Geobacter metallireducens*), manganese (e.g., *Deferribacter thermophilus*), reduced sulfur compounds (e.g., *Desulfuromusa kysingii*), and fumarate (e.g., *Desulfuromonas acetexigens*). Furthermore, some species transfer electrons to heavy metals (e.g., uranium, chromium), graphite electrodes, humic substances, or chlorinated compounds (e.g., tetrachloroethene, trichloroacetic acid). The vast majority of Fe(III)-reducing prokaryotes utilizes fermentation end products such as acetate, ethanol, or hydrogen as electrons donors. Only few prokaryotes are known to couple the dissimilatory reduction of Fe(III) to the oxidation of sugars (e.g., *Acidiphilium*

cryptum), amino acids (e.g., *Geothermobacter ehrlichii*), long-chain fatty acids (e.g., *Desulfuromonas palmitatis*), monoaromatic compounds (e.g., *Geobacter metallireducens*), or reduced inorganic sulfur compounds (e.g., *Acidithiobacillus ferrooxidans*).

Acidophilic Fe(III)-reducing bacteria

A variety of autotrophic and heterotrophic bacteria that thrive in environments of low pH (<3) can grow by dissimilatory Fe(III) reduction (Johnson, 2007). All known species are facultative anaerobes, and most of them synthesize cell compounds required for dissimilatory Fe(III) reduction only in the absence of oxygen. In contrast, some species of acidophilic Fe(III)-reducing bacteria (e.g., *Acidiphilium cryptum*) constitutively express all genes necessary for Fe(III) reduction (Johnson, 2007). This is surprising because the redox potential of the redox pair O_2/H_2O reaches values above +1,000 mV below a pH value of 3 (Appelo and Postma, 2007). Hence, cells gain more energy by aerobic respiration than by utilizing Fe(III) as terminal electron acceptor (redox potential of the redox pair Fe^{3+}/Fe^{2+} : +770 mV).

Several species of acidophilic Fe(III)-reducing bacteria (e.g., *Acidithiobacillus ferrooxidans*, *Sulfobacillus acidophilus*) also grow by oxidizing Fe(II) with molecular oxygen; such prokaryotes were shown to catalyze the cycling of iron in laboratory experiments (Johnson et al., 1993). So far no representative of the domain *Archaea* was described to grow by dissimilatory Fe(III) reduction at acidic pH values.

Neutrophilic Fe(III)-reducing prokaryotes

The majority of dissimilatory Fe(III)-reducing prokaryotes that were isolated and characterized thrives at circumneutral pH and has to cope with a poorly soluble electron acceptor under natural conditions. In addition, the redox potential of the redox pair Fe(III)/Fe(II) is much lower (+100 to –300 mV, depending on the type of ferric iron oxide) than the redox potential of the redox pair O_2/H_2O (+820 mV) relevant for aerobic respiration. Therefore, at neutral pH, Fe(III) is a less valuable electron acceptor in terms of energy generation than molecular oxygen. Similarly, prokaryotes gain more energy from the respiration with nitrate or manganese as terminal electron acceptors. Hence, respiratory Fe(III) reduction at neutral pH occurs only under anoxic conditions in the absence of more favorable electron acceptors (Canfield et al., 2005). In some studies on neutrophilic Fe(III)-reducing prokaryotes, only chelated forms of ferric iron such as Fe(III) citrate or Fe(III) NTA (nitrilotriacetate) were applied. Caution is necessary in the interpretation of results from such studies because chelated Fe(III) forms are soluble at circumneutral pH, have redox potentials that are higher than those of non-chelated Fe(III) minerals, and may react rather unspecifically with electron-releasing cell compounds (Straub et al., 2001).

Most research on the biochemistry of microbial Fe(III) reduction focuses on members of the genera *Shewanella*

and *Geobacter*, two genera with significant differences in their basic physiology. *Shewanella* species are facultative anaerobes that belong to the *Gammaproteobacteria*. They grow very well in nutrient-rich medium and oxidize lactate or pyruvate incompletely to acetate. In contrast, species of the genus *Geobacter* belong to the *Deltaproteobacteria* and most of them are described as anaerobes. The most common electron donors utilized by *Geobacter* species include acetate, ethanol, and hydrogen. Despite differences in basic physiological features, various *c*-type cytochromes play a significant role in intracellular electron transfer processes in both *Shewanella* and *Geobacter* species.

Mechanisms of prokaryotic Fe(III) reduction

Considering the phylogenetically widespread ability of prokaryotes to reduce Fe(III) and the great prokaryotic physiological diversity, it is not surprising that Fe(III)-reducing prokaryotes developed different strategies to cope with Fe(III) as electron acceptor. According to experimental observations, prokaryotes developed the following strategies to transfer electrons from the cell to the surface of Fe(III) minerals: (a) Physical contact between cell and mineral surfaces allows for direct delivery of electrons; an attachment of cells to Fe(III) minerals has been repeatedly reported and seems to be the prerequisite for the delivery of electrons to Fe(III) in some Fe(III)-reducing prokaryotes such as *Geobacter metallireducens*. (b) Iron chelators increase the solubility of ferric iron; some evidence indicates that *Shewanella algae* and *Geothrix fermentans* produce and release Fe(III) chelators specifically during growth with Fe(III) minerals. (c) Electron-shuttling compounds accomplish the transfer of electrons from the cell to the mineral; diffusible electron-shuttling compounds help to bridge the spatial distance between cells and ferric iron (Lovley et al., 2004; Kappler and Straub, 2005). Reduction of Fe(III) by electron shuttling compounds is of particular importance in natural habitats where prokaryotic cells and Fe(III) minerals are not evenly distributed and Fe(III) might not be directly/physically accessible for prokaryotic cells. Naturally occurring electron-shuttling compounds that were shown to sustain prokaryotic growth include humic substances (Lovley et al., 1996) and sulfur compounds (Straub and Schink, 2004). Note that prokaryotes which reduce Fe(III) only via naturally occurring electron-shuttling compounds are no Fe(III)-reducing prokaryotes in a strict sense as their actual electron acceptor is the shuttling molecule and not Fe(III).

Summary

Phylogenetically diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to reduce Fe(III) during fermentative or respiratory growth by the transfer of electrons. Fe(III)-reducing prokaryotes have been recovered or detected in a great variety of pristine or contaminated habitats, and their widespread occurrence correlates well with the ubiquitous presence of Fe(III) minerals. Only one electron can be disposed

by the reduction of Fe(III) to Fe(II) and hence Fe(III)-reducing prokaryotes have to reduce large quantities of Fe(III) to sustain cell metabolism. Due to the complex geochemistry of iron, acidophilic and neutrophilic Fe(III)-reducing prokaryotes have to cope with different iron species: Fe(III) minerals are soluble only below a pH value of 3. At circumneutral pH, Fe(III) is only poorly soluble and significantly less energy can be gained by Fe(III) respiration compared to aerobic respiration. However, Fe(III) is the dominant electron acceptor in many anoxic habitats and prokaryotes developed different strategies for its utilization.

FERMENTATION

Fermentation is a route of obtaining energy from the oxidation of organic substrates using an endogenous electron acceptor (usually an organic compound). The energy yield in fermenting systems is limited when compared to respiration. Nevertheless, fermentation still allows growth under conditions when external, inorganic electron acceptors are lacking, or when iron as part of the electron carriers in the respiratory chain is not available and therefore an electron transport chain cannot be synthesized. Common fermentation substrates are sugars, which are present in large amounts in the environment, for example, as photosynthesis products and constituents of plant cell wall material. Microbial sugar fermentation pathways encompass lactic acid fermentation, alcoholic fermentation, and propionate fermentation, according to the major metabolic products generated. Another important fermentation pathway is acetoclastic methanogenesis, that is, fermentation of acetate to CO₂ and CH₄, which is performed by some methanogenic archaea (see entry “[Methane, Origin](#)”). [Hydrogen](#) is another common product of microbial fermentation processes.

Definition

FISH (fluorescence in situ hybridization) is a hybridization technique employing reverse complementary

fluorescently labeled probes to detect and localize only those parts of the chromosome, a gene or its transcript with which they show a high degree of sequence similarity. Results are mostly evaluated by either fluorescence microscopy or cell sorting methods like flow cytometry. Depending on target gene, probe chemistry, labeling, and combination with other analytical tools, a wide range of different FISH applications can be employed for advanced in situ analysis of community structure, dynamics, localization, activity, function and interactions of different cellular species.

Introduction

Antonie van Leeuwenhoek's ingenious improvement of the microscope in the seventeenth century revolutionized biology as this initiated novel ways to explore our world and ultimately led to the discovery of a new dimension of life forms, the microorganisms. However, since traditional microscopy reveals mainly structural features, its usefulness to advanced biological research reached its limits with the beginning of the molecular era. Fortunately, new possibilities for advanced microscopy applications emerged with the parallel development of two techniques: (1) in situ hybridization techniques (ISH) employing labeled gene probes targeting specific regions of a particular gene, and, (2) fluorescence microscopy. Fluorescence in situ hybridization (FISH) makes use of reverse complementary gene probes labeled with fluorochromes that are hybridized to specific regions on a chromosome (e.g., a specific gene) of gene transcripts (e.g., rRNA), and are then viewed by fluorescence microscopy or evaluated by other cell sorting methods like flow cytometry. FISH revolutionized nearly all disciplines in microbiology, in particular environmental research fields like microbial ecology, environmental biotechnology and geomicrobiology, since this enabled a cultivation-independent exploration of whole cells of culturable as well as not yet cultured microorganisms in their natural, complex environment (Amann et al., 1995; Amann and Fuchs, 2008). However, along with the development of other novel molecular tools and the growing comprehension of the enormous complexity of the biology of microorganisms, the first generation of FISH tools reached its limits as well, especially for applications on oligotrophic ecosystems characterized by a low amount of cells with often low activities in a strongly confounding background, which is often the case in geomicrobiology. Different modifications of the first generation FISH protocol as well as different combinations with other analytical tools were undertaken in order to meet the increasing demands with respect to, e.g., improved targeting of cells with low ribosome content or probe-repelling cell wall chemistry, alternative strategies to increase probe specificities or signal intensities, advanced image analysis, elucidation of activity and function by targeting other genes than the 16S rRNA gene and combining with different analytical tools, and finally cell enrichment of probe-targeted cells for,

e.g., subsequent identification by sequencing (Wagner et al., 2003; Wagner et al., 2006; Amann and Fuchs, 2008; Orphan, 2009; Wagner, 2009). The development of novel FISH protocols in combination with other advanced analytical tools and microscopes is most likely to continue to play a crucial role in microbial ecology and geomicrobiology research. Only microscopy-based tools can provide us with the possibility to visualize the morphotype, growth characteristics, spatial distribution, and interactions of different taxa on a single cell level within complex communities. Furthermore, despite all progress in nucleic acid-based approaches like PCR and the "omics" approaches, only microscopy-based tools can link isolated extracted DNA/RNA markers, with intact, individual cells in their natural environment, and thus also exclude molecular biases often observed with nucleic acid extraction and PCR (Table 1). The greatest benefit will be reached when combining different FISH tools with various methods such as cultivation and molecular approaches. Ultimately, a systematic approach can be undertaken to reveal discrepancies between different tools caused by extant biases of each tool in terms of sensitivity and specificity, so that a validated, advanced insight into the true diversity, dynamics, function, activities, and relationships in the microbial world can be obtained.

Sample preparation, fixation and storage of samples

In contrast to nucleic acid-based tools, which simply require either addition of preservative agents or instant freezing of biomass and storage in sterile tubes for subsequent nucleic acid extraction, preparation of samples for FISH requires usually more consideration and effort, especially for long-term storage of samples of unknown microbial composition and/or employing certain types of FISH protocols that may disrupt the original structure of the sample.

Preparations for standard applications

1. *Sampling strategy*: While FISH may principally work equally well on nearly any kind of optimally fixed cells with high ribosome content, irrespective of cell titers or the nature of the environmental sample, our abilities to detect, visualize, and quantify the cells may be obstructed by tedious, time-consuming screening of samples with either too low or too high cell counts, confounding background caused by autofluorescence of the background or unspecific binding of probes or labels to nontarget cells/substances (Amann and Schleifer, 2001). Some of these problems can be minimized by considering how the sample should be optimally treated already during sampling, for example, by concentration, dilution, embedding, cell extraction, or particular consideration on chemical-physical conditions to avoid cells getting exposed to stress.
2. *Fixation time and protocols*: The purpose of the fixation is to maintain the original microbial composition

Fluorescence In Situ Hybridization (FISH), Table 1 Advantages and disadvantages of FISH versus disruptive tools like PCR with ribosomal biomarkers

Diagnostic possibilities	PCR/qPCR/RT PCR	FISH ^a
<i>Experimental conditions:</i>		
Preparation of biomass prior to analysis	Nucleic acid extraction	Fixation of cells ^b
Long-term storage of sample	−80°/−20°C	−20°/+4°C ^b
Labor time (after NA extraction or fixation)	>6 h	0.5 h to 96 h
<i>Relevant parameters for microbial ecology:</i>		
Quantify distribution and dynamics	Yes/partly	Partly
Link targeted gene directly to cells	No	Yes
Visualize morphology and growth characteristics	No	Yes
Visualize associations with other microorganisms	No	Yes
Three-dimensional reconstruction of complex aggregates	No	Yes
<i>Methodological strengths/weaknesses:</i>		
Simultaneous identification of several genes	Only with multiplex PCR	Yes ^c
Distinguish gene targets in live/inactive/dead cells	No (for DNA)	Partly ^d
Distinguish false-positive gene products (chimera)	No	Yes
Quick check of cultures for purity	No	Yes
Enrich for subsequent analysis (e.g., sequencing)	Yes	Partly
Amplification biases	Yes	No ^e
Quantification bias caused by multiple ribosomal gene copies	Yes (for qPCR)	No
Bias caused by unspecific target binding	Possible	Possible
Biases caused by matrix	Inhibition	Autofluorescence
Detection limit	>5 gene copies	10 ^{5–7} cells/ml ^f

^aIncluding different FISH protocols and advanced microscopy tools.

^bIn certain cases, samples may be stored at −80°C and the fixation omitted (Yilmaz et al., 2010b).

^cOnly with certain FISH protocols like mRNA-CARD FISH, RING-FISH, gene-FISH, and in situ RCA.

^dDepends on the FISH protocol and how this is combined with other analytical tools and appropriate references.

^eException, FISH protocols based on PCR.

^fDepends on concentration/dilution procedure.

of the samples as well as the morphological integrity of cells during the different hybridization steps (elevated temperature, exposure to enzymes, detergents and osmotic gradients) and prevent cell losses, while simultaneously making the cells permeable for the probe(s) (Amann, 1995). Unfortunately, there is not one plain fixation protocol for all cell types for all different FISH protocols. Different fixation protocols have been developed to cope with the complexity of archaea, bacteria, and Eukarya with regard to their cell envelope packages and the type of probes to be employed for a particular FISH protocol. A suboptimal fixation protocol may make cells impermeable for probes or even cause cell lysis, especially during longer storage times or when exposing the cells to certain procedures such as incubation with enzymes prior to the FISH procedure. Apart from the selection of an optimal fixative reagent, it is also relevant to pay attention to the concentration of the fixative reagent and the incubation time and conditions. Fixation times may range from a few min up to >24 h, depending on cell type and FISH protocol, and are generally followed by a washing step for removal of the fixative reagent. The two most common fixation procedures are based on either aldehydes (e.g., formalin, paraformaldehyde (PFA), glutaraldehyde) or on alcohols (e.g., ethanol, methanol). In the

majority of cases, Gram-negative cells within the domain Bacteria are usually fixed with 4% PFA, and Gram-positive cells within the domain Bacteria with ice cold 96% ethanol (Amann, 1995). To a certain extent, some Gram-negative species will also tolerate EtOH fixation, and some Gram-positive species (general exceptions are, e.g., *Actinomycetes* and *Streptococci*) may also tolerate PFA fixation (especially if the incubation time is short, see, e.g., de los Reyes et al., 1997). The previously mentioned fixation protocols may also work well for certain Archaea and Eukarya species, but in some cases, especially for certain Archaea species (Nakamura et al., 2006) or eukaryotes like fungi (Baschien et al., 2001; Tsuchiya and Taga, 2001; Weber et al., 2007) or protozoa, see, e.g., Fried et al. (2002); Petroni et al. (2003); Fried and Foissner (2007); Weber et al. (2007), other fixative reagents or post treatments with enzymes like chitinase or endo-isopeptidase are more suitable. When dealing with unknown samples, it is therefore recommended to explore the suitability of different fixation protocols. Irrespective of the fixation protocol used, the cells must be fixed as soon as possible with optimally prepared fixation solutions, preferably already during the sampling occasion to avoid population shifts and for optimal evaluation of true probe signal intensities as these

may in certain cases also serve as an indicator of activity (see, e.g., Wagner et al., 1995; Molin and Givskov, 1999; Rossetti et al., 2007).

3. *Storage of fixed cells:* Fixed samples (in wet or dry state, such as on a microscope slide or on a membrane filter) can be stored at room temperature or at +4°C for shorter periods. For optimal long-term storage at -20°C, fixed cells are generally dissolved in a 1:1 (v/v) solution with a 50% end concentration of ethanol in order to avoid freezing (Amann et al., 1994). Cells concentrated on a membrane filter are normally stored dry at -20°C (e.g., Teira et al., 2004). So far, no systematic studies on the maintenance of cell integrity or ribosome content in fixed cells after longer storage periods exist, but it is generally recommended that once the cells have been fixed, quantitative studies should be performed within days to avoid biases caused by unknown deterioration of cells or decrease of ribosome content.

Preparations for omics-based applications

For genomic or proteomic applications, unfixed biomass is desirable to minimize possible sequencing biases introduced by cross-linking and to avoid possible cell lysis difficulties, so that FISH targeted cells can be enriched by, e.g., flow cytometry and subjected to, e.g., whole genome application. Recently, Yilmaz et al. (2010b) demonstrated that the standard oligonucleotide FISH protocol can also be performed on at least two different types of frozen, non-fixed complex environmental samples using Archaea as well as Bacteria targeted probes. However, more research is needed to explore further possibilities as well as limits of this approach, such as if this is quantitative and if this applies to any kind of cells types or other environmental samples, irrespective of growth and storage conditions, as well as if this approach is also suitable for other types of FISH protocols.

FISH for in situ detection of ribosomal genes

General background: The ribosomal gene was and will at least for the near future remain the standard gene for reconstruction of phylogeny, despite the growing amount of genome sequences which is presently revolutionizing our current concepts of taxonomy, phylogeny, and development of comprehensive biomarkers for improved identification (see, e.g., Konstantinidis et al., 2009). The main benefits of the ribosomal gene is that it is a functionally conserved molecule present in high numbers in all organisms from all domains and is composed of sequence regions of higher and lower evolutionary conservation. The variable conservation degree makes it particularly ideal for design of biomarkers for nucleic acid-based detection and quantification of different levels of microbial diversity (Ludwig et al., 1998; Priesse et al., 2007; Amaral-Zettler et al., 2008; Yarla et al., 2008). Although several different types of ribosomal subunits exist, only a few of these are currently used as targets for probes in

FISH studies. For most FISH studies, the main gene target is the 16S rRNA gene for prokaryotes, and the 18S-rRNA gene for eukaryotes (Ludwig et al., 1998; Metfies et al., 2008). However, other multicopy ribosomal genes or even stable multicopy RNA molecules have been (5S-rRNA, tmRNA), or may be occasionally used as alternative targets for FISH probes (23S-rRNA, 28S-rRNA, precursor rRNA, intergenic spacer region). These alternative gene targets may overcome some of the problems occasionally encountered when targeting the 16S rRNA gene, such as low information content and limited probe accessibility or information about activity status (Trebesius et al., 1994; Oerther et al., 2000; Schmid et al., 2001; Schonhuber et al., 2001; Zimmermann et al., 2001; Peplies et al., 2004). However, despite this, the 16S rRNA gene has remained the main gene target in FISH applications, especially for environmental systems with unknown diversity, since the 16S rRNA gene is nowadays routinely sequenced in most studies so that the amount of retrieved 16S rRNA gene sequences has thus come to outrange all other databases of other gene sequences.

Principle of FISH: The FISH procedure generally consists of the following steps (Adapted from Manz et al., 1992 and Amann, 1995):

1. Optional: For certain cases an additional post-treatment of the fixed/non-fixed biomass may be needed for increased permeabilization of probes through rigid cell envelope packages, or for removal of confounding background, by, e.g.:
 - Incubation with enzymes like lysozyme, protease, proteinase K, mutanolysine, endoisopeptidase, chitinase
 - Removal of wax or chemical precipitates by chemical solvents
 - Use of detergents (SDS) or other chemicals like hydrochloric acid
 - Physical treatment like exposure to microwave radiation
 - Addition of chemicals to avoid dissolution of essential compounds
2. Successive dehydration in an EtOH series (50%, 80%, 96%, each step between 1–3 min).
3. Hybridization of the fixed sample with the probe on a microscope slide or in solution under stringent conditions (Figure 1). Stringent conditions are achieved by keeping the hybridization temperature constant (+46°C) but varying the formamide concentration for different probes (Stahl and Amann, 2001).
4. Subsequent washing with preheated buffered washing solutions at a slightly higher temperature (+48°). After this, the hybridized samples can be evaluated or stored at dark prior to evaluation (for a shorter period at room temperature or at +4°, for longer periods, at -20°C).
5. Optional: Counter stain with, e.g., an appropriate nucleic acid stain like DAPI (4',6-diamidino-2-phenylindole) or SYBR Green (e.g., Wagner et al., 1994, or Engel et al., 2003).

Fluorescence In Situ Hybridization (FISH), Figure 1 (a) Schematic outline of the standard oligonucleotide FISH procedure on microscope slides. (b) Schematic outline of a cell before and after the standard oligonucleotide FISH procedure.

6. Evaluation is achieved by:

Visualization:

- Standard epifluorescence microscopy, or confocal laser scanning microscope for three-dimensional reconstruction (Wagner et al., 1998).
- Combination with other microscopes like electron microscopy (e.g., Gerard et al., 2005), RAMAN spectroscopy combined with a microscope (Wagner, 2009), or nanoSIMS (Behrens et al., 2008; Orphan, 2009).

For digital image analysis of FISH images, various software packages are available, such as CMEIAS, COMSTAT, and daime (Heydorn et al., 2000; Daims and Wagner, 2007; Zhou et al., 2007; Daims, 2009).

Other options:

- Membrane-based evaluation (e.g., dot blot, Wagner et al., 1994).
- Combination with other analytical tools (e.g., screening of uptake of radioactive tracers or stable isotopes

(Nielsen et al., 2005; Orphan, 2009) or other FISH protocols targeting non-ribosomal genes or their transcripts for exploring activities or functions.

- Reverse hybridization by microarray technology, where multiple probes are deposited on a support material to hybridize a labeled sample with the probes (DeSantis et al., 2005; Loy and Bodrossy, 2006; Taylor et al., 2010).
- Cell sorting or probe signal intensity evaluation by flow cytometry (Behrens, 2003; Amann and Fuchs, 2008), RING (Recognition of Individual Genes)-FISH (Zwirgmaier et al., 2004b), or magneto-FISH (Orphan, 2009).
- Whole genome amplification (Orphan, 2009; Yilmaz et al., 2010b).

Basic equipment and reagents for standard FISH applications:

- Hybridization oven (46°C)
- Water bath (48°C)
- Polypropylene screw top tubes, filter paper

- Reagents (for chemical composition, check, e.g., Amann, 1995):
 - NaCl
 - Tris/Phosphate buffer
 - EDTA
 - SDS
 - Formamide
 - 50%, 80%, 96% EtOH
 - Reagents/equipment for improved probe accessibility
- Labeled probes
- Counterstains like nucleic acid stains (e.g., DAPI (4',6-diamidino-2-phenylindole) or SYBR Green)
- Microscope slides (possibly coated with, e.g., poly-L-lysine (Sigma-Aldrich, www.sigmaaldrich.com/sigma-aldrich/home.html) or a gelatine-chromium sulphate solution (Amann, 1995))
- Mounting medium of appropriate pH (e.g., from Citifluor, www.citifluor.co.uk/; Vectashield, www.vectorlabs.com/; various mounting media from Invitrogen, www.invitrogen.com/site/us/en/home.html)
- Some form of fluorescence microscope.

FISH probes (probe design, probe evaluation, probe databases)

For a proper interpretation of FISH experiments, probes need to be optimally designed and handled. Several different types of softwares (e.g., the ARB software package, (www.arb-home.de/) and Primrose (www.bioinformatics-toolkit.org/index.html)) and detailed guidelines for probe design for particularly FISH experiments exist (Amann, 1995; Amann and Schleifer, 2001; Stahl and Amann, 2001), and (Hugenholtz et al., 2001). Below follows an updated summary of some of those guidelines, focusing mainly on applications with the ARB software package:

1. Construction of a molecular data base: Prior to all probe design, a comprehensive data base of all relevant complete gene sequences of the target group and relevant nontarget groups should be collected for a thorough evaluation of phylogenetic relationships. Partial sequences may also be included, but these should be handled more critically due to their limited value for a full evaluation of all potential probe targets. Sequences can be downloaded from different categories of databases: (1) all kinds of gene sequences: EMBL (www.embl.de/), NCBI (www.ncbi.nlm.nih.gov/), (2) regularly updated and curated ribosomal gene sequences: RDP (<http://rdp.cme.msu.edu/>), SILVA (www.arb-silva.de/), Green Genes (<http://greengenes.lbl.gov/cgi-bin/nph-index.cgi>); the ribosomal internal spacer collection (<http://egg.umh.es/rissc/>); (3) functional genes: Fun Gene (<http://fungene.cme.msu.edu/index.spr>). Principally, most softwares that can align sequences, perform phylogenetic evaluations, and design biomarkers like PCR primers can be used for FISH probe design as well.

However, the bioinformatic software package ARB (www.arb-home.de/) using the curated SILVA database (www.arb-silva.de/) is highly recommended, as several useful and partly unique tools have been implemented into this package to facilitate a straightforward and advanced design, evaluation and visualization of probes and their target (Ludwig et al., 2004; Kumar et al., 2005; Kumar et al., 2006; Priesse et al., 2007).

2. Hierarchic probe design strategy: Where possible, it is recommended to design a hierarchic probe set consisting of several probes targeting different phylogenetic levels of the target organism/group (see, e.g., Amann and Schleifer, 2001; Amann and Fuchs, 2008). If the different probes are labeled with different fluorochromes and combined in one FISH experiment on a mixture of cells with different phylogenetic relationships, different overlaps of the probes will produce different color combinations depending on the taxonomical relationships. This facilitates a straightforward top to bottom identification of the taxonomical status (e.g., from phylum down to species level) of different cell species in a complex sample (Amann, 1996).
3. General rules for standard oligonucleotide probe design:
 - (a) Select the appropriate gene sequences of the desired target group. Depending on bioinformatic software, design the probe according to the recommended procedure. For example, if using the ARB software (Ludwig et al., 2004), select from the menu "probe design" an appropriate PT server, then define appropriate parameters such as length of probe (average length of probes for standard oligonucleotide probes is between 15–25 nucleotides), minimum group and maximum non-group hits, GC content, melting temperature range, range of nucleotide positions, and maximum hair-pin bonds.
 - (b) The selected probe should be completely specific (complementary) to a region of the selected target sequences and have at least one mismatch to the same target region in nontarget sequences. Optimally, the mismatch should be centralized in the nontarget sequences in order to maximize the destabilizing effect of the mismatch.
 - (c) Perform probe match to evaluate the specificity of the probe (e.g., in the bioinformatic software package ARB (www.arb-home.de/), the RDP Probe Match tool (<http://rdp.cme.msu.edu/probematch/search.jsp>), the probeBase probeCheck tool (<http://131.130.66.200/cgi-bin/probecheck/content.pl?id=home>) or general data bases like the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov/).
 - (d) Unfortunately, there is no such thing as a perfect probe that only targets the target group as the course of the evolution of gene sequences is a random process. During a recent review Amann and Fuchs (2008) showed that it is more advisable to

evaluate group coverages as the percentage of group members that can be identified relative to the total number of members in the target group. With this approach, three groups can be distinguished: true positives; false negatives; and false positives. Parallel to the constantly growing amount of gene sequences, the coverage of each probe target group is ultimately going to change and possibly demand more complex probe sets. For example, in the early days of the FISH technology, only one probe was needed to target all recognized species in the Bacteria domain (Amann et al., 1990). However, a decade later, Daims et al. (1999) showed that a mixture of three different Bacteria domain targeting probes were needed to cover all so far (up till 1999) recognized sublineages.

- (e) Evaluate the melting temperature of the probes (e.g., as described by (Hugenholtz et al., 2001) or the probeBase, www.microbial-ecology.net/probebase/). Optimally, the probe should have a melting temperature $> 57^{\circ}\text{C}$. If the melting temperature is $< 57^{\circ}\text{C}$, the temperature can be increased by shifting the position of the probe or expanding the length of the probe.
 - (f) Check probe accessibility. A reoccurring problem is the probe accessibility. The general explanation for is that certain regions of the secondary structure of the ribosomal gene are inaccessible for probes. Unfortunately, the accessible and inaccessible regions of the ribosomal molecules appear to vary from species to species, so that only precise estimations of probe accessibilities can be made for those species where a systematic probe accessibility mapping has been performed (see, e.g., Fuchs et al., 1998; Behrens, 2003a, 2006b). The general recommendation is therefore to design probes on different target positions and then to simply explore on a trial-and-error experimental basis which of the selected probes produce high probe signals. However, Yilmaz et al. (2006) showed that principally all positions on the ribosome molecule may yield satisfying probe signals if a sophisticated approach based on a thermodynamics-based probe design is employed. With this approach, FISH experiments of any given probe can be mathematically simulated. Based on this, theoretical predictions on, e.g., the probe accessibility, the formamide denaturation profile, and the potential of mismatch discriminations can be made (for further details see Yilmaz et al., 2010a). Based on this, further optimizations of the probe accessibility can be made such as modifying the length of the probe or the experimental hybridization conditions (e.g., increase of the hybridization time up to 96 h).
 - (g) Check for potential self-complementarity of the probe which may initiate duplex formations between the probe and the target (e.g., caused by hairpins or dimers).
 - (h) Naming of probe. There are three types of nomenclatures for probes: (1) the short name (e.g., EUB 338), which is often constructed by a shortage of the name of the target group (e.g., EUB for Eubacteria), followed by a number that denotes the first position of the probe on the target gene (e.g., nucleotide position 338 on the *E. coli* gene); (2) a name based on a comprehensive nomenclature to denote main features of the probe such as the target gene, target group, target group level, 3' end of the probe, and probe length (Alm et al., 1996); and (3) the probeBase accession number (e.g., pB-00159 for probe EUB 338) as assigned by the online probe database ProbeBase (www.microbial-ecology.net/probebase/).
4. Labeling of probes: The first rRNA-targeted oligonucleotide probes for FISH were radioactively labeled, developed by microautoradiography and evaluated by light microscopy (Giovannoni et al., 1988). Unfortunately, the work with radioactively labeled probes restricted the applicability of FISH. However, the applicability of FISH increased as soon as the first fluorescently labeled rRNA-targeted oligonucleotide probes were reported (DeLong et al., 1989). Probes are nowadays generally covalently labeled at the 5' end of the oligonucleotide, and the most commonly used fluorochromes for FISH are sulfoindocyanine fluorochromes like Cy3 and Cy5, fluorescein, ALEXA probes, rhodamine, and Texas red. The criteria for selecting appropriate fluorochromes are based on the capabilities of the available epifluorescence microscope and on the nature of the cells and their surrounding environment, where the aim is to avoid a confounding background and unspecific binding of fluorochromes to nontarget cells, and/or to minimize bleaching of probe signals. During the last decade, several different approaches have been used to increase the probe signal intensities in those cases where standard labeled probes produce too weak fluorescent signals. A simple strategy was to employ mixtures of mono-labeled probes targeting different sites of the ribosomal gene (e.g., Amann et al., 1990; Krumholz et al., 1990; Morris et al., 2002; Sunamura and Maruyama, 2006). Another strategy is to employ alternative labeling procedures of oligonucleotide probes, such as polynucleotide FISH (e.g., Trebesius et al., 1994), horseradish peroxidase (employed in catalyzed reporter deposition (CARD-FISH), e.g., Pernthaler et al., 2002a; Wendeberg, 2010) or various types of multiple labeling of probes (Amann and Schleifer, 2001) such as DOPE-FISH (Stoecker et al., 2010).
 5. Purchase and handling of probes: Probes are chemically synthesized and can be purchased with or without label. In earlier times, probes had to be manually labeled (Amann, 1995), but nowadays labeled probes can be easily purchased from most providers (e.g., Biomer, Invitrogen, MWG, SIGMA) of molecular reagents like PCR primers at a rather low cost (starting

from approximately 50 USD). Probes are normally shipped in lyophilized stage and must be dissolved in either sterile water or an appropriate buffer (depending fluorochrome chemistry) to a stock solution of normally 100 pmol/μl. It is recommended to store aliquots of working solutions in individual tubes in dark at -20°C, and to avoid excessive freeze-thawing of the aliquots. For long time storage or transport at room temperature it is recommended to lyophilize the probes.

6. Evaluation of probes:

(a) For any purchased probe, it is recommended to check for the probe's concentration, length, homogeneity, and the completeness of the labeling, to avoid unwanted competition between labeled and unlabeled probes for target sites as this may reduce the probe signal intensity. This can be done as described by Stahl and Amann (2001), or as recommended by the provider who performed the labeling.

(b) Newly designed probes are generally first tested under non-stringent conditions (i.e., by excluding formamide in the hybridization buffer). If positive probe signals are obtained in reference strains as expected, stringent conditions of the probe should be determined by an increasing formamide series, as described in Amann and Schleifer (2001). Probe signal intensities can be quantified by digital image analysis with, e.g., the daime software, as described by (Daims et al., 2009).

(c) Combination of probes. The great advantage of FISH over standard PCR applications is that several differently labeled gene probes can be simultaneously combined and thus enable a simultaneous identification of different probe-targeted species within a complex sample. The general guidelines for optimal combination of different probes are:

- Probes with identical formamide concentrations for optimal stringencies (at which the probe hybridizes to the specific target but not to nontarget groups) can be combined in the same hybridization experiment.
- Probes with different formamide concentrations for optimal stringencies cannot be combined in the same hybridization experiment. Instead, successive hybridizations must be performed for each probe, starting with the probe with the highest formamide concentration.

(d) Most standard epifluorescence microscopes are equipped with filter sets that allow separate recording of at least two to three differently labeled probes and one UV-based nucleic acid stain like DAPI (4',6-Diamidino-2-phenylindol). Such recorded images can then be merged into one image with image analysis software packages. However, recent developments based on, e.g., advanced confocal laser scanning microscopes with multichannel image analysis, special tools such as spectral imaging or FISH protocols employing quantum dot

labeled probes allow the simultaneous combination of a considerably higher amount of differently labeled probes (e.g., Ainsworth et al., 2006; Anderson, 2010; Bentolila et al., 2006).

7. Probe bases: Different attempts to construct databases with FISH probes have been made during the last two decades. However, the probeBase (www.microbial-ecology.net/probebase/) is currently the most regularly updated data base for ribosomal targeted probes, encompassing 2,568 different probes targeting species within Archaea, Bacteria, and, to some extent, Eukarya (further probes targeting protists and cyanobacteria can be retrieved from www.sb-roscoff.fr/Phyto/Data-bases/RNA_probes_introduction.php) for FISH as well as for ~16 different microarray applications (version September 2010). Here, many of the so far published probes can be easily searched by different criteria (target organism, target sites, probe name, probe sequence, probeBase accession number, references). Detailed information about the probe chemistry are listed and links are provided for online probe matches to other databases like the ProbeCheck (<http://131.130.66.200/cgi-bin/probecheck/content.pl?id=home>), Green Genes (<http://greengenes.lbl.gov/cgi-bin/nph-index.cgi>), or RDP (<http://rdp.cme.msu.edu/>). Furthermore, up to 150 ribosomal gene sequences retrieved from own clone libraries can be uploaded to screen for probes targeting these sequences (Loy et al., 2007, 2008).
8. Controls: For a valid evaluation of probe signals, three different categories of controls are needed: (1) Positive controls where probes are employed that should or should not overlap with the intended target gene. (2) Negative controls, to explore the impact of confounding background caused by, e.g., autofluorescence, and of nonspecific binding of fluorochrome or probe to target cells as well as nontarget cells. To achieve this, two different negative controls are recommended: exclusion of probes during the hybridization experiment, and application of negative reference probes like the NON-SENSE probe (Loy et al., 2002) or the non-EUB probe (reverse complementary to the EUB probe, (Wallner et al., 1993)). (3) All experiments should be performed on appropriate optimally fixed strains carefully selected to serve as positive as well as negative controls.
9. Other probe types: Note that some of the rules applied for design and handling of standard oligonucleotide probes may not be applicable to other probe types, like polynucleotide probes, PNA FISH probes, or CARD FISH probes.

General guidelines for evaluation and presentation of FISH results

For optimal interpretation of FISH experiments, several parameters should be considered, as outlined below. Omitting any of these principles may lead to false interpretations of FISH results.

Checklist for optimal FISH experiments and evaluation of results:

1. Were optimal sampling strategies, fixation protocols, and storage conditions employed?
2. Were appropriate reference strains used simultaneously in parallel with the FISH experiments? If strains are lacking, clones based on CLONE-FISH (Schramm et al., 2002) may also be used to experimentally evaluate the FISH experiments.
3. Were the microscopical investigations performed with optimal microscope settings?
4. Were appropriate probes/probe combinations (positive as well as negative controls) used under stringent conditions?
 - (a) If the probe signals were positive, explore if nonspecific probe signals can be unequivocally excluded or if the identity of the probe signal can be confirmed with other measures.
 - (b) If the probe signals were negative on the sample subject to investigation but otherwise positive with positive controls, explore if this is caused either by cell losses during the hybridization procedure, low cell numbers in the original sample, or low activity (and thus low ribosome content and probe signal intensity).
5. If quantifications of FISH images were performed, explore if the amount of sample applied to the microscope slide was appropriate. A too high or too low cell concentration may result in an over- or underestimation of cell numbers. Evaluate also if the amount of microscope slide fields investigated was high enough to ensure statistical evaluations of error ranges. For further evaluation of quantification, spiking of sample may be recommendable (SPIKE-FISH, Daims et al., 2001).
6. When presenting FISH results, it is recommended to describe results as "cells targeted by probe X," instead of uncritically identifying the probe signals with the intended target group of the probe. This is especially important when applying probes to samples with unknown microbial composition and the applied probe is known to target false-positive as well as false-negative species and no further means have been undertaken to confirm the identity by, e.g., appropriate combinations of hierarchic FISH probe sets or subsequent sequencing (Amann and Fuchs, 2008).
2. Confounding background caused by auto-fluorescing compounds like photosynthetic pigments, proteins like cofactors (e.g., F420 for methanogens), other parameters in the surrounding environment (e.g., precipitates, fibers, minerals, humic substances); or by unspecific absorption of fluorochrome label.
3. Probe technical problems (e.g., probe permeabilization problems, probe accessibility in the ribosomal gene, probe specificity).
4. Limited information content of the 16S rRNA gene for taxonomical resolution of closely related species.
5. Limited possibilities to confirm true identity and explore phylogenetic relationships and identify novel gene groups or species.
6. Limited information on in situ physiology in terms of:
 - (a) Activity status (high ribosome content may reflect exponential growth stage, but this appears to be species dependent and needs to be explored for each particular species group (Wagner et al., 1995; Molin and Givskov, 1999; Rossetti et al., 2007);
 - (b) Function, since the ribosomal gene does not reveal information about function and since the genotype is not always linked to the phenotype (e.g., many functional microbial groups are polyphyletic, such as methanogens, sulphate reducers, denitrifiers, cyanobacteria, spirochaetes, reductive dechlorinators);
 - (c) Limited possibilities to monitor gene expressions (mRNA transcripts) or proteins.
7. Applications limited to prokaryotic and eukaryotic cells. However, the first notes on successful FISH applications on bacteriophages (personal communication, K. Zwirgmaier, D. Scanlan, A. Millard, University of Warwick, UK) was recently made with the Recognition of individual genes [RING]-FISH protocol (Zwirgmaier et al., 2004b).

To overcome these limitations, several different strategies have been employed, ranging from modifying different parts of the procedures of the first-generation FISH protocol, searching for alternative gene targets, probe chemistries and labeling procedures, to combining FISH with other markers (e.g., activity stains, enzymes, isotopes), analytical procedures, and advanced microscopes or other analytical tools for evaluation of several different parameters for a holistic interpretation of in situ microbial ecology. Today, at least four categories of advanced FISH strategies can be recognized, which can be combined in a multitude of ways for various novel applications.

Category I – increasing the probe signal intensity:

Drawbacks of oligonucleotide FISH and the benefits of novel FISH technologies

The first generation of FISH protocol based on oligonucleotide probes revolutionized nearly all disciplines in microbiology. However, along with applications of this protocol on different ecosystems and species, many of the limits of the first-generation FISH protocol became obvious:

1. Successful detection dependent on ribosome content (minimum 370 ± 16 rRNA molecules per *E. coli* cell (Hoshino et al., 2008)).
- Incubate sample prior to fixation with substrates or stress-promoting compounds like chloramphenicol (Kalmbach et al., 1997; Ouverney et al., 1997).
- Employ non-fluorescent labeling of probes for increased detection of cells in, e.g., a strongly autofluorescing background based on, e.g., radiolabels (Giovannoni

et al., 1988); or enzymes (Zarda et al., 1991; Amann et al., 1992; Lim et al., 1993).

- Employ alternative probe design based on helper probes for oligonucleotide probes to increase probe accessibility (Fuchs, 2000).
- Employ alternative probe chemistries for increased hybridization efficiencies and specificities based on peptide nucleic acid probes (PNA) (Perry-O'Keefe et al., 2001), or locked nucleic acid (LNA) probes (Kubota et al., 2006a).
- Explore probe accessibilities and thermodynamics-based probe design to predict probe accessibilities and optimal hybridization conditions (Yilmaz et al., 2006; Yilmaz et al., 2010a), and/or in nucleotide or probe quenching (Behrens, 2003; Behrens et al., 2004; Wagner et al., 2003).
- Employ self-ligating probes to overcome background autofluorescence and avoid washing steps (Sando and Kool, 2002).
- Employ PCR-generated probes to generate polynucleotide probes (Trebesius et al., 1994; Zimmermann et al., 2001; Meisinger et al., 2007; Pernthaler, 2002; Preston et al., 2002; Moraru et al., 2010).
- Employ modified fluorescent labeling technologies based on horse radish peroxidase labeled probes and catalyzed reporter deposition (CARD)-FISH (Pernthaler et al., 2002a, b; Hoshino et al., 2008; Pavlekovic et al., 2009); multiple labeling of probes (Amann and Schleifer, 2001; Stoecker et al., 2010) or quantum dot conjugated probes (Bentolila et al., 2006).

Category II – exploring activity or function:

- Combine FISH with rRNA dot slot to quantify cellular rRNA content (Ravenschlag et al., 2000).
- Employ FISH probes targeting the precursor 16S rRNA gene and intergenic spacer regions (Oerther et al., 2000; Schmid et al., 2001; Moter et al., 2010).
- Combine FISH with different activity indicating stains like redox dyes (Nielsen et al., 2003), halogenated thymidine analogue bromodeoxyuridine (BrdU) (Pernthaler et al., 2002), exo-enzyme labeled probes (Xia et al., 2007), or antibodies to target cell surface markers or proteins (Currin et al., 1990; Lubeck et al., 2000; Gmür and Lüthi-Schaller, 2007).
- Incubate sample with radioactively labeled substrates or stable isotopes to explore specific uptake of labeled substrates by micro-autoradiography (Nielsen et al., 2005), RAMAN spectroscopy (Wagner, 2009), or nano-SIMS (Behrens et al., 2008; Orphan, 2009).
- Target functional genes or even the mRNA gene by CARD-FISH (Wagner et al., 1998; Pernthaler and Amann, 2004; Orphan, 2009; Pilhofer et al., 2009), two-pass TSA-mRNA FISH (Kubota et al., 2006b), or by alternative labeling (Coleman et al., 2007).
- Target functional genes. For this, there are two categories: (1) PCR-generated probes like polynucleotide

FISH (Moraru et al., 2010) or (2) amplification of the target sequence like in situ PCR (Hodson et al., 1995; Rodríguez-Castaño, G., 2008; Tani et al., 1998), in situ loop-mediated isothermal amplification (Maruyama et al., 2003); recognition of individual genes [RING]-FISH (Zwirgmaier et al., 2004b; Pratscher et al., 2009; Hauer et al., in preparation), in situ rolling-circle amplification (Maruyama et al., 2005; Hoshino et al., 2010), cycling primed in situ amplification (CPRINS, Kenzaka, 2005; Tamaki et al., 2005), circularizable probes (Zhang et al., 2006), circularizable probes (Zhang et al., 2006; Hoshino et al., 2010), peptide nucleic acid assisted rolling circle amplification FISH (Smolina et al., 2007), and polynucleotide FISH (Moraru et al., 2010).

Category III – combining FISH with advanced cameras, microscopes, or other analytical tools:

- CCD camera (Amann and Schleifer, 2001); confocal laser scanning microscopy (Wagner et al., 1998), and advanced digital image processing (Daims, 2009; Daims and Wagner, 2007)
- Electron microscopy (Kenzaka et al., 2005; Ishidoshiro et al., 2005)
- Spectral imaging (Ainsworth et al., 2006)
- RAMAN spectroscopy (Wagner, 2009)
- nanoSIMS (Behrens et al., 2008; Orphan, 2009)
- Atomic force microscopy (Huang et al., 2009)

Category IV – enrichment of FISH targeted cells for subsequent analyses, and combination with high-throughput technologies:

- Automatic cell sorting and enrichment techniques based on flow cytometry (Amann and Fuchs, 2008)
- Magneto-FISH (Orphan, 2009; Stoffels et al., 1999)
- RING-FISH (Zwirgmaier et al., 2004a)
- Whole genome amplification (Yilmaz et al., 2010b)

Many of these improvements minimize at least some of the drawbacks observed with the first generation FISH protocol; however, these new approaches do also introduce other drawbacks. For example, CARD-FISH has replaced the standard FISH protocol in several cases because it produces stronger probe signals (Pernthaler et al., 2002a, b) and just recently it was shown that it can be combined with polynucleotide probes targeting functional genes in a subsequent step (Moraru et al., 2010). Nevertheless, compared to standard oligonucleotide FISH, CARD-FISH is a rather time-consuming FISH protocol and allows only the application of one probe per hybridization experiment. Furthermore, as peroxidase can be found in nearly all organisms, there may be a risk for unspecific probe reactions. Fortunately, the peroxidase can be denatured prior to the FISH procedure, however, optimal denaturation conditions appear to be species dependent and may thus require individual optimizations (Pavlekovic et al., 2009). Similarly, the recent developments of various protocols to target non-ribosomal genes

like various functional genes and mRNA transcripts, or combining with various analytical tools, present different advantages as well as disadvantages. For example, considerable higher costs, advanced equipment, tedious protocols, loss of probe specificity, less flexibility in terms of combination with other probes or protocols or on various organisms, problems with adequate preservation of gene target due to high decay rate (e.g., precursors or mRNA), or unpredictable cross-reactions (e.g., when incubating a complex community with radioactive substrates or stable isotopes). However, irrespective of these drawbacks that may eventually be overcome in future, it is crucial to keep in mind that our greatest hindrance for successful, unequivocal interpretations of FISH experiments in the environment is the unknown biodiversity and multitude facets of dynamics and interactions, which paradoxically seem to grow with each advancement in the science of microbiology. Thus, it appears likely that the development of novel FISH technologies will continue in parallel with the development of novel tools and our increased understanding of microbial diversity.

Different FISH applications in geomicrobiology

The fields explored in geomicrobiology are extremely diverse, ranging from the deep biosphere to the atmosphere surrounding our planet Earth, and from there to the outer space. The conditions for the different ecosystems will therefore vary tremendously so that different sampling technologies and modifications of FISH protocols must be employed in order to achieve successful FISH results. So far, FISH has not been employed in geomicrobiology as often and as successfully as in other microbiological fields like environmental biotechnology (e.g., wastewater treatment plants, Nielsen et al., 2009) or in medical sciences (e.g., Bridger et al., 2010). This is because many of the ecosystems explored in geomicrobiology are often exposed to extreme conditions and generally contain low amounts of usually novel microorganisms with slow or unknown growth rates. Furthermore, special considerations must be made in terms of interpreting results with regard to the risk of contamination of samples during sampling (e.g., during drilling experiments) and to the impact of geochemical conditions on so far published FISH protocols. Because of these obstacles, many of the recent advanced developments of FISH protocols have actually been driven by microbial ecologists and geomicrobiologists (Orphan, 2009). Below follow some examples of how FISH has been employed for some of the most widely explored ecosystems in geomicrobiology (see also images in Figure 2):

Aquatic systems: In general, successful FISH experiments can be performed on aquatic systems, since at least one of the main parameters for good microbial growth and dispersion of cells and nutrients, water, is abundant. Nevertheless, several parameters may introduce several biases, e.g., low nutrient status and/or naturally occurring

autofluorescing particles (Vesey et al., 1997). Aquatic systems with high nutrient content such as contaminated lakes or even anthropogenic systems like wastewater treatment plants will contain greater amounts of highly active bacteria than oligotrophic systems like aquifers and thus produce stronger FISH probe signals. For improved FISH on oligotrophic systems, different approaches have been undertaken:

Aquifers/ground water/drinking water: These ecosystems are generally dominated by planctonic cells in rather low cell numbers due to extreme conditions like oligotrophy, different redox states (e.g., anaerobic conditions), or toxic compounds (e.g., heavy metals, chlorinated drinking water or contaminated aquifers). Due to this, the general turn-over activities and thus also the ribosome content in the cells are generally extremely low. For adequate FISH evaluation, samples often need to be concentrated (e.g., by filtration) and confounding precipitates or debris removed (e.g., by cell extraction, Caracciolo et al., 2005). Early studies reported that standard FISH protocols may work well on certain aquatic samples like lakes and bottled water (Pernthaler et al., 1998; Glöckner et al., 2000; Watanabe et al., 2000; Flies et al., 2005; Loy et al., 2005); however, more recent studies report that either rainbow FISH (Sunamura and Maruyama, 2006) or CARD-FISH are more recommendable on drinking water or groundwater (Sekar et al., 2003; Nielsen et al., 2006; Wilhartitz et al., 2007; Meisinger et al., 2010a).

Ocean: Similar to the freshwater systems mentioned above, oceanic ecosystems are generally dominated by planctonic cells in rather low cell numbers. However, in contrast to the conditions in the aquifers in the subsurface, the cells in oceans are often exposed to more dynamic conditions. Despite this, the ribosome content in the cells and the turn-over activities may be rather low at least for certain species – depending on location and other conditions such as oxygen concentration, light frequencies, redox conditions, nutrient conditions, flux rates. For adequate FISH evaluation of cells, samples often need to be concentrated (e.g., by filtration) and confounding precipitates or debris must be removed (e.g., by cell extraction). Early studies demonstrated that standard FISH protocols may work well (Murray et al., 1998; Glöckner, 1999; Cottrell and Kirchman, 2000; Morris et al., 2004); however during the last decade, most studies have tried to increase probe signal intensities by modifying standard FISH protocols or applying other FISH tools like polynucleotide FISH (DeLong et al., 1999; Pernthaler et al., 2002; Preston et al., 2002) or CARD-FISH (Pernthaler et al., 2002a; b; Ishii et al., 2004; Teira et al., 2004; Herndl et al., 2005). In addition to this, various combinations with different activity targeted studies based on incubation with chloramphenicol (Ouverney and Fuhrman, 1997), radioactive substrates like thymidine (Pernthaler et al., 2002) or bromodeoxyuridine (BrdU, Pernthaler and Pernthaler, 2005), or other substrates such as amino acids

Fluorescence In Situ Hybridization (FISH), Figure 2 (Continued)

Fluorescence In Situ Hybridization (FISH), Figure 2 Demonstration of different images from different ecosystems produced by different FISH techniques.

(Ouverney and Fuhrman, 2000; Cottrell, 2000; Cottrell, 2003), have been undertaken.

Soil/sediments/subseafloor: Soil and sediments are rather difficult environments for successful FISH studies, as these habitats are extremely diverse, complex, and subject to harsh and fluctuating conditions in terms of, e.g., water content and redox conditions. Thus, more than most other ecosystems, the biosphere of microorganisms in soil is often characterized by micro-niches which may be exposed to dramatic changes with regard to space and time. In addition to this, many substances in soil or sediments produce strongly confounding background such as humic compounds, mineral precipitates or other microscopic particles of unknown character. For successful FISH experiments, two different main approaches have been made (for a review, see Schmid et al., 2006; Schmid et al., 2007): (1) Spatial separations of cells or micro-niches by approaches such as embedding and

sectioning of soil columns or by confocal laser scanning microscopy of soil aggregates, different cell extraction procedures such as density centrifugation or cation exchange membranes (McDonald, 1986; Smith and Stribley, 1994; Caracciolo et al., 2005; Kurola et al., 2005; Lunau et al., 2005; Bertaux et al., 2007), or flow cytometry (Kalyuzhnaya et al., 2006; Podar et al., 2007). (2) The second approach employed a variety of different FISH protocols. The early studies reported generally only partial success or even contradictory results between FISH and other analytical tools (Hahn et al., 1992; Ludwig et al., 1997; Zarda et al., 1997; Chatzinotas, 1998; Llobet-Brossa et al., 1998; Christensen, 1999; Hristova et al., 2000; Ravensschlag et al., 2000; Janvier et al., 2003; Kobabe et al., 2004; Rusch and Amend, 2004; Flies et al., 2005; Knittel et al., 2005). However, during the last years, most studies have now replaced the standard FISH tool with CARD-FISH and nanoSIMS (Ishii et al., 2004;

Mussmann et al., 2005; Schippers et al., 2005; Tal et al., 2005; Orphan 2009).

Karst regions/rock/deep biosphere: During the last decade, our understanding of the role of microorganisms and their interactions with rocks and minerals over geological timescales has expanded considerably. The interaction of minerals with water and microbes do not only influence soil fertility, transport compounds, and pollutants through the subsurface, but they also contribute to dissolution of rocks or precipitation of various mineral formations like speleothems in caves and may thus even play a key role in global climate change (Northup and Lavoie, 2001; Brown and Lee, 2007; Cockell and Herrera, 2008). Several attempts have been made to screen for microbial life in rocks and set up validated guidelines for this (Barton et al., 2001; Barton et al., 2006; Tobin et al., 1999). The reoccurring concern is to not only prove extant microbial processes (Orphan and House, 2009) but also current cellular-based in situ activities in often carbon-poor systems. Since it may be difficult to retrieve sufficient amounts of RNA or other activity biomarkers from these systems due to low cell counts and activities, FISH, in particular in combination with advanced tools like nanoSIMS, may play a crucial role for demonstrating whole cells with targetable genes (Orphan, 2009). Despite these obstacles, standard FISH as well as CARD-FISH protocols have been successfully applied on, e.g., microbial mats in association with water and energy-rich substances for life based on chemolithoautotrophy in rocky environments or caves (Engel et al., 2003; Macalady et al., 2006; Meisinger et al., 2007; Meisinger et al., 2010b). However, certain types of microbial mats may be strongly hampered by confounding background caused by various mineral precipitates (Engel et al., 2010; Koeberich, 2008). Rigid environments like calcified biofilms or speleothems thus demand sophisticated modifications of standard FISH protocols as well as CARD-FISH (e.g., Shiraishi et al., 2008).

Extremophiles in various geological environments: Extremophiles thrive in extreme ecosystems which are characterized by extreme physical or geochemical conditions. Such conditions may pose a particular challenge for FISH experiments. So far, FISH has only been practiced in certain types of extremophilic ecosystems with mixed success, e.g., in hot springs (Nubel et al., 2002; Simbahan et al., 2005; Nakagawa et al., 2006; Weidler et al., 2008), polar regions (Junge et al., 2004), halophilic systems (Rossello-Mora et al., 2003; Maturano et al., 2006), mines/bioleaching systems (Schrenk et al., 1998; Edwards et al., 1999; Bond et al., 2000; Takai, 2002; Baker et al., 2004), hydrothermal vents (Harmsen et al., 1997; Schrenk et al., 2003; Nakagawa et al., 2006), and methane hydrate seeps (Boetius and al, 2000).

Summary

FISH (fluorescence in situ hybridization) is a valuable tool for in situ identification of microbial community structure, cell morphology, dynamics and spatial distribution.

If combined with different analytical tools additional information of activity, function and interactions of different species on single cell level can be performed. However, for successful FISH experiments, it is crucial to optimize and validate all steps throughout the FISH protocol, ranging from proper sampling technique and fixation, selection of appropriate gene markers, hybridization conditions and relevant controls, to optimal detection and evaluation strategies.

FORAMINIFERA

Alexander V. Altenbach
 Ludwig-Maximilians-University Munich, Munich,
 Germany

Synonyms

Forams (for short)

Definition

Foraminifera (from ancient Greek “hole bearers”, refers to the pores that early observers recognized in the calcitic tests) are amoeboid, eukaryotic protists with a large network of very thin cytoplasm extrusions (reticulopodia). Most species produce a genetically fixed shell (test), made of organic matter, agglutinated particles, calcite, aragonite, high-magnesium calcite, or opaline silica. The tests may be either simple bowls or tubes, or branched, coiled, substructured, and ornamented in diverse complexity. Several thousand species are found living in modern oceans, and this number still increases. Several times more extinct species are recovered from the fossil record. Foraminifera are considered an order (sometimes a class) in paleontology, subdivided by the structure and composition of modern and fossil tests. They are ranked among the “Granuloreticulosa” in biology, characterized by (1) their branching and anastomosing networks of reticulopodia, (2) a rapid bidirectional transport of intracellular granules and membrane domains driven by specific tubulin assemblies, and (3) a complex alternation of sexual and asexual reproductive cycles. Genetic investigations led to the definition of the first rank group “Foraminifera” within the Supergroup “Rhizaria”. Independent from such rankings, they range among the most common, diverse, and ubiquitous groups of single celled, test building eukaryotes on earth.

Introduction

Numerous foraminiferal species indicate specific environmental conditions, and the first and last appearance of extinct species exactly indicates time intervals in earth history. Investigations on the chemical and isotopical composition of their calcitic tests reveal environmental drifts in global ice volumes, palaeo-temperatures and -salinities of marine water masses, and marine palaeo-productivity (Hemleben et al., 1989; Murray, 2006). Despite the long term and extensive attention on foraminifera in

taxonomy (Loeblich and Tappan, 1988) and environmental sciences (Sen Gupta, 1999), our comprehensions on their evolution and ecophysiology are still in transition. Molecular ecology and metagenomics applied to the study of microbial biodiversity are changing our view of the biosphere. An impressive extension of foraminiferal clades has been uncovered by such molecular tools: naked freshwater amoebians, naked marine giant amoebians, and giant deep-sea protists formerly considered of unknown origin, where added to the first rank group Foraminifera (Adl et al., 2005; Pawlowski and Burki, 2009). Even amoeboid parasites of terrestrial plants are supposed to reach out from this lineage (Archibald and Keeling, 2004). Efforts to couple the growing phylogenetic diversity of single-celled organisms with ecological function lead to the discovery of novel metabolisms, processes, and symbiosis, and thus to a reevaluation of the geobiochemical impact of pro- and eukaryotes (Moya et al., 2008).

Earth history

The earliest fossils presumed for the foraminiferal lineage reach back into the Mesoproterozoic, despite severe problems in defining even Ediacaran remainders (Dong et al., 2008). The Cambrian provides already several foraminiferal families with organic-walled or agglutinated tests (Benton, 1993). A significant eukaryote radiation occurs in the Ordovician, coincident with increasing nutrient supply, enhanced primary production, and the propagation of planktonic metazoan stages. Such amplified planktonic food chains sponsored increased flux rates of organic matter at the sea floor, and thus the radiation of planktotrophy (Nützel et al., 2006). The calcitic fusulinids start in the Silurian (Loeblich and Tappan, 1988), and extend into the first rhizarian, rock forming mass deposition of biogenic shallow water carbonates, from the Pennsylvanian to the Permian. The fusulinid clade develops all principal morphological adaptations known from modern benthic foraminifera sheltering phototrophic symbionts, thus these mass deposits should result from host–symbiont interactions (Anderson and Lee, 1991). The structure of modern marine primary production was based on the evolution of diatoms, coccoliths, and modern dinoflagellates in the Triassic to Jurassic (Falkowski et al., 2004). Restructuring and enhancing marine primary productivity to an elevated level is recorded by the boost of rotaliid foraminifera, modern metazoans, and increasing bioturbation (Martin et al., 2008). One tribe of calcitic foraminifera, the globigerinids, completely adapted to this new planktonic food chain, and started to enter a purely pelagic live style in the Middle Jurassic. The boost of rock forming biogenic carbonate (chalk) and silica (diatomite) production from these new planktonic systems, however, was delayed to the Cretaceous in the marine realm, and to the Eocene for lacustrine diatomites. The first major radiation of planktonic foraminifera occurred during the mid-Cretaceous. The density structure of the upper water

Gold, Figure 2 Laser scanning micrograph (ex. 488 nm, em. 543 nm) of microorganisms (green) on a gold grain (red) from the Eder River, Germany. Eubacteria labeled by oligonucleotide probe EuB-CY3.

and not in the surrounding sediments. With a similarity of 99%, the sequence correlated to *Cupriavidus (Ralstonia) metallidurans*. Ninety percent of the bacteria in the laboratory experiment died because of the toxicity of AuCl_4^- . The surviving cells adapted themselves to the high concentration of Au(III) ions and precipitated gold. In addition to morphological studies (Bischoff, 1997), this provides evidence for bioaccumulation of secondary gold (e.g., nuggets, gold grains) by bacteria like *C. metallidurans* (Figure 2).

The basal biochemical microbial processes of the biomineralization of gold are not completely understood yet. Precipitation of gold provides the cellular defense of *C. metallidurans* and is controlled by a coupling of efflux, reduction and possibly methylation of gold complexes (Reith et al., 2009). Reith et al. (2007) have published a comprehensive review of the geomicrobiology of gold.

Summary

Different microorganisms are partially resistant to dissolved gold. Various microbial activities precipitate gold. Biofilms of *Cupriavidus metallidurans* accumulate gold naturally and contribute to the formation of secondary gold.

GONDWANALAND, FORMATION

Joseph G. Meert
 University of Florida, Gainesville, FL, USA

Definition

Gondwanaland or “Gondwana” is the name for the southern half of the Pangaeen supercontinent that existed some 300 million years ago. Gondwanaland is composed of the major continental blocks of South America, Africa,

Arabia, Madagascar, Sri Lanka, India, Antarctica, and Australia (Figure 1). The name “Gondwana” is derived from a tribe in India (Gonds) and “wana” meaning “land of.” Gondwanaland is superficially divided into a western half (Africa and South America) and an eastern half (India, Sri Lanka, Madagascar, Antarctica, and Australia).

The archetypal view of Gondwanaland assembly was an Ediacaran–Cambrian-age coalescence of East Gondwana (India, Sri Lanka, Madagascar, Australia, and Antarctica) with West Gondwana (South America and Africa) along the Mozambique Belt (labeled East African Orogen in Figure 1). “Pan-African” tectonothermal belts outside of the Mozambique Belt (~500–600 Ma) were well-known at the time, but they were often treated as zones of ensialic activity rather than sites of continental collision. Although this rather simplistic view of Gondwanaland assembly is now strongly debated, the polyphase assembly model outlined below is not completely accepted (see Yoshida, 2007).

A new view of Gondwanaland assembly began with the work by Stern (1994) who demonstrated clear evidence of juvenile arc development and accretion in the Arabian–Nubian shield and continental collision to the south in Kenya and Tanzania. In the early 1990s, work by Dalziel (1991), Hoffman (1991), and Moores (1991) hinted that

the assembly of Gondwanaland followed the breakup of an earlier supercontinent called Rodinia (see Chapter *Breakup of Rodinia*). Although the exact continental configuration of Rodinia is still debated (for example, Meert and Torsvik, 2003), the assembly of West Gondwana is more or less viewed as a polyphase accretion of formerly disparate blocks while East Gondwana is generally treated as a coherent unit from ~1,100 Ma until its breakup in the Mesozoic (Meert, 2003). More recently, Fitzsimons (2000), Meert (2003), Collins and Pisarevsky (2005), and Kelsey et al. (2008) noted that at least two “Pan-African” age mountain belts cut across the East Antarctic shield and juxtapose distinct crustal fragments thought to comprise the East Antarctic “Grenvillian craton.” The existence of these belts preclude a united East Gondwana and favor a polyphase accretion of major blocks to form Greater Gondwanaland in the Cambrian. In this scenario, the assembly of Gondwanaland was accomplished along three major orogenic belts known as the Brasiliano, East African, and Kuungan orogenies (Figure 1). Additional data supporting a polyphase assembly of East Gondwana are derived from paleomagnetic and geochronologic studies.

No matter what the exact model of Gondwanaland assembly is, the formation of this supercontinent followed

Gondwanaland, Formation, Figure 1 The Gondwanaland supercontinent. The cratons comprising West Gondwana are shaded in light blue and those comprising East Gondwana are shaded in yellow. Neoproterozoic orogenic belts crisscross the supercontinent. Those associated with the final amalgamation of the supercontinent are the East African Orogen (750–620 Ma; red), the Brasiliano-Damara Orogen (630–520 Ma; blue), and the Kuungan Orogen (570–530 Ma; green).

shortly after the extreme glaciations during the late Neoproterozoic (Hoffman et al., 1998) and was nearly synchronous with the rapid evolutionary pulse that coincides with the Ediacaran and Cambrian radiations. Final assembly of Gondwanaland and a circum-Gondwanaland mountain chain is thought to have provided nutrients to the oceanic realm and also resulted in a large $^{87}\text{Sr}/^{86}\text{Sr}$ spike due to the erosion of the mountains (Squire et al., 2006). Therefore, links between the assembly of the Gondwanaland supercontinent and biological evolution are forwarded by numerous studies (Meert and Lieberman, 2008).

GREAT OXYGENATION EVENT (GOE)

The term “Great Oxygenation Event” (GOE, also known as “Great Oxidation Event,” “oxygen catastrophe,” or “oxygen crisis”) describes a critical environmental change in Earth history that resulted from the appearance of diatomic oxygen (O_2), a waste product of oxygenic photosynthesis, in the atmosphere. The GOE occurred around 2.4 billion years (Ga) before present, close to the boundary between the Archean and the Proterozoic (2.5 Ga). For details, please refer to “[Critical Intervals in Earth History](#).”

GREEN ALGAE

Green algae are photosynthetic eukaryotes with simple plastids (derived from primary endosymbiosis) that are mostly microscopic and rarely more than a meter in greatest dimension. The approximate 6,000 extant species show an enormous diversity of growth habit and fine details of their cellular architecture. Green algae occur as unicellular or colonial, microscopic or macroscopic, motile planktonic, as well as benthic attached forms. Some (e.g., Dasycladales) are important carbonate producers in aquatic environments, others live in symbiotic associations with fungi to form lichens in terrestrial settings. Green algae living as endosymbionts inside heterotrophic organisms are a common phenomenon. The order Charales, in which full tissue differentiation occurs, is considered to include the closest relative of higher plants. For details, please refer to entry “[Algae \(Eukaryotic\)](#).”

Definition

Fe(II)-oxidizing prokaryotes. Diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to oxidize Fe(II), ferrous iron, to Fe(III), ferric iron. The electrons obtained from the oxidation of Fe(II) are utilized for energy generation in aerobic or anaerobic respiration and/or for assimilative reduction reactions.

Introduction

Aerobic neutrophilic Fe(II)-oxidizing bacteria were among the first environmentally relevant prokaryotes that were discovered and studied in the nineteenth century. At that time, eye-catching ochre deposits in ponds and slowly running waters had attracted the attention of microbiologists. Microscopic analyses of such ochre deposits revealed the prevalence of twisted stalks and/or sheaths that were covered with iron minerals. Bacteria were suggested to be responsible for the production of these specific iron-covered structures, and subsequently the first aerobic Fe(II)-oxidizing prokaryotes were described: *Gallionella ferruginea* and *Leptothrix ochracea* (reviewed by Emerson, 2000; Canfield et al., 2005). In contrast, the anaerobic oxidation of Fe(II) by phototrophic bacteria (Widdel et al., 1993), nitrate-reducing bacteria

(Straub et al., 1996), and archaea (Hafenbradl et al., 1996) was not discovered until the end of the twentieth century. Aerobic and anaerobic Fe(II)-oxidizing prokaryotes play decisive roles in the biogeochemical cycle of iron. In comparison to other physiological groups, only few species of Fe(II)-oxidizing prokaryotes are available in pure culture. The capability to oxidize Fe(II) is apparently phylogenetically widespread because the known species belong to diverse phyla of the *Bacteria* and the *Archaea*. The mechanism(s) of prokaryotic Fe(II)-oxidation are largely unknown (Canfield et al., 2005).

Geochemical aspects of Fe(II)

Iron is the fourth most abundant element in the Earth's crust, and depending upon the geochemical conditions, it occurs either in soluble forms or in a variety of minerals (Cornell and Schwertmann, 2003). In natural habitats, Fe(III) minerals are reduced to Fe(II) mainly by the metabolic activities of prokaryotes. The concentration of dissolved Fe(II) is controlled by precipitation-dissolution reactions and by adsorption processes: Fe(II) precipitates with carbonates, phosphates, or sulfides and tends to adsorb to soil particles and mineral surfaces (Cornell and Schwertmann, 2003; Canfield et al., 2005). Chemical reoxidation reactions of Fe(II) depend on the pH and on the presence of appropriate oxidants. The reaction rate of Fe(II) with molecular oxygen is very low at acidic pH values, and hence Fe(II) is fairly stable in the presence of oxygen under acidic conditions. With increasing pH, the reaction rate of Fe(II) and molecular oxygen increases, and at fully aerated conditions Fe(II) is rapidly oxidized to ferric iron (Emerson, 2000; Canfield et al., 2005). In the absence of molecular oxygen, Fe(II) can be chemically oxidized at appreciable rates only by nitrite or Mn(IV). However, Mn(IV) minerals are insoluble, and the environmental significance of these nondiffusible oxidants is therefore limited (Canfield et al., 2005). It is thus

speculated that anaerobic Fe(II)-oxidizing prokaryotes are important catalysts for the reoxidation of Fe(II) in anoxic environments.

Fe(II) as electron donor in aerobic or anaerobic respiration

Dissimilatory Fe(II)-oxidizing prokaryotes utilize Fe(II) as electron donor in aerobic or anaerobic respiration, i.e., they gain energy by coupling the oxidation of Fe(II) to the reduction of molecular oxygen or to the reduction of nitrate. As in the oxidation of Fe(II) to Fe(III), only one electron can be obtained, dissimilatory Fe(II)-oxidizing prokaryotes have to oxidize large quantities of Fe(II) to gain enough energy for maintenance and growth. Today, three physiological groups of prokaryotes are known to grow with Fe(II) as electron donor: acidophilic aerobic, neutrophilic aerobic, and neutrophilic nitrate-reducing prokaryotes. Due to energetic considerations, the oxidation of Fe(II) with nitrate at low pH values should also yield enough energy for prokaryotic growth. However, acidophilic Fe(II)-oxidation coupled to the reduction of nitrate has not been reported so far (Kappler and Straub, 2005; Appelo and Postma, 2007). The dissimilative oxidation of Fe(II) leads to the formation of Fe(III) minerals which are well soluble under acidic conditions but barely soluble at neutral pH. Hence, neutrophilic Fe(II)-oxidizing prokaryotes have to cope with a virtually insoluble metabolic end product.

Acidophilic aerobic Fe(II)-oxidizing prokaryotes

A variety of autotrophic and heterotrophic prokaryotes that thrive in environments of low pH (< 3) were described to grow by dissimilatory aerobic oxidation of ferrous iron (Johnson, 2007). At acidic pH values, Fe(II) is stable in the presence of molecular oxygen, and hence prokaryotes do not need to compete with the chemical oxidation. However, the energy gain of acidophilic aerobic Fe(II) oxidation is low because the redox potential of the redox pair $\text{Fe}^{3+}/\text{Fe}^{2+}$ is with +770 mV rather high. The difference to the redox potential of the redox pair $\text{O}_2/\text{H}_2\text{O}$ (> +1,000 mV below pH 3) allows therefore only little energy generation (Kappler and Straub, 2005; Appelo and Postma, 2007). Nevertheless, representatives of different phyla of the *Bacteria* (e.g., *Acidithiobacillus ferrooxidans*, *Sulfobacillus acidophilus*) and the *Archaea* (*Acidianus brierleyi*, *Sulfolobus metallicus*) exploit Fe(II) in aerobic respiration. Moreover, three species of the genus *Leptospirillum* are obligate aerobic Fe(II)-oxidizing bacteria, i.e., Fe(II) is the only electron donor and molecular oxygen the only electron acceptor utilized (Johnson, 2007). All other acidophilic Fe(II)-oxidizing prokaryotes make use of alternative electron donors (e.g., hydrogen, sulfur) and sulfur or Fe(III) as alternative electron acceptors. Species of acidophilic Fe(II)-oxidizing bacteria that also grow by dissimilatory reduction of Fe(III) were shown to catalyze the cycling of iron in laboratory experiments (Johnson et al., 1993).

Acidithiobacillus ferrooxidans was the first acidophilic aerobic Fe(II)-oxidizing bacterium that was isolated (Temple and Colmer, 1951); it belongs to the *Gammaproteobacteria* and is so far the best studied of all acidophilic prokaryotes. However, details of the flow of electrons from Fe(II) to molecular oxygen are still debated. Apparently, Fe(II) is oxidized on the cell surface at the outer membrane. Subsequently, a variety of membrane-bound and periplasmic cytochromes plus the periplasmic copper protein rusticyanin transfer the electrons to a cytochrome *c* oxidase. There the electrons are used together with protons to reduce molecular oxygen to water (Johnson, 2007; Castelle et al., 2008).

Neutrophilic aerobic Fe(II)-oxidizing bacteria

So far, only few representatives of the *Alpha*-, *Beta*-, and *Gammaproteobacteria* are described to grow by dissimilatory aerobic oxidation of Fe(II) at neutral pH. This physiological group gains more energy than their acidophilic counterparts because the difference between the redox potentials of the relevant redox couples is greater at neutral than at acidic pH values ($\text{Fe(III)/Fe(II)} < +100$ mV; $\text{O}_2/\text{H}_2\text{O} +820$ mV; Kappler and Straub, 2005; Appelo and Postma, 2007). However, in oxic environments of neutral pH Fe(II) has a half-life in the order of few minutes and is chemically oxidized to ferric iron (Canfield et al., 2005). This competition with the chemical oxidation is likely the major reason why neutrophilic aerobic Fe(II)-oxidizing bacteria thrive preferentially in microoxic niches or oxic/anoxic boundaries. Laboratory studies showed that the activity of Fe(II)-oxidizing bacteria contributes up to 90% to the formation of Fe(III) under such conditions. Typical habitats for neutrophilic aerobic Fe(II)-oxidizing bacteria include groundwater springs, freshwater, and marine hydrothermal vents, wetlands, and plant rhizospheres (Emerson, 2000). Due to their production of conspicuous iron-encrusted twisted stalks or sheaths, *Gallionella ferruginea* and *Leptothrix ochracea* were the first Fe(II)-oxidizing bacteria that were already discovered in the nineteenth century. Only during the past few years, additional morphologically inconspicuous aerobic Fe(II)-oxidizing bacteria were isolated, e.g., *Ferritrophicum radicola* and *Sideroxydans paludicola* (Canfield et al., 2005; Weiss et al., 2007). According to physiological studies, several of the novel strains are obligate aerobic Fe(II)-oxidizing bacteria, i.e., Fe(II) is the only electron donor and molecular oxygen the only electron acceptor utilized (Weiss et al., 2007).

Neutrophilic anaerobic Fe(II)-oxidizing nitrate-reducing prokaryotes

Under anoxic conditions, bacteria (*Alpha*-, *Beta*-, *Gamma*- and *Deltaproteobacteria*) and archaea (*Archaeoglobales*) are capable of oxidizing Fe(II) with nitrate as the terminal electron acceptor. At pH 7, all redox pairs of the nitrate reduction pathway can accept electrons from Fe(II), because their redox potentials are more positive than that

of the iron redox couple (Straub et al., 1996). Nitrate-dependent Fe(II) oxidation was reported for diverse habitats such as rice paddy soil, activated sewage sludge, freshwater or marine sediments (Canfield et al., 2005). The first observation of this metabolism was made with a freshwater enrichment culture: Fe(II) was oxidized to Fe(III) and nitrate was concomitantly and stoichiometrically reduced to molecular nitrogen (Straub et al., 1996). As Fe(II) was the sole electron donor supplied, Fe(II) oxidation coupled to nitrate reduction definitely supported cell growth in this enrichment culture. The situation is not so clear in most pure cultures of Fe(II)-oxidizing nitrate-reducing bacteria (e.g., *Acidovorax* sp. strain BoFeN1 or *Thermomonas* sp. strain BrG3) because they need an organic co-substrate for growth. In such strains it is questioned whether Fe(II) oxidation is beneficial and supports cell growth or whether Fe(II) is just oxidized in a rather unspecific side reaction. All known species are able to utilize alternative electron donors (e.g., hydrogen, organic acids) and alternative electron acceptors (nitrite, oxygen, ferric iron). *Geobacter metallireducens*, isolated as Fe(III)-reducing bacterium, couples the oxidation of Fe(II) to the reduction of nitrate to ammonium; it is unclear if *G. metallireducens* obtains energy by this process (Lovley et al., 2004; Canfield et al., 2005). *Ferroglobus placidus* is so far the only representative of the domain *Archaea* that grows by coupling the dissimilatory oxidation of Fe(II) to the reduction of nitrate to nitric oxide and nitrogen dioxide. Alternatively, *F. placidus* utilizes hydrogen, sulfide, acetate, or monoaromatic compounds as electron donor and thiosulfate or Fe(III) as electron acceptor (Hafenbradl et al., 1996; Lovley et al., 2004).

Fe(II) as electron donor for assimilative reduction reactions

Various groups of prokaryotes are able to reduce oxidized inorganic compounds for the synthesis of biomass. Such assimilative reduction reactions require a source of electrons (Canfield et al., 2005). Phylogenetically and physiologically different groups of chemotrophic and phototrophic prokaryotes have the ability to exploit Fe(II) as source of electrons for assimilative reduction reactions such as the fixation of carbon dioxide. Chemotrophic acidophilic and neutrophilic, aerobic and anaerobic Fe(II)-oxidizing prokaryotes have been discussed before because they oxidize the major fraction of Fe(II) during respiratory energy generation. In contrast, phototrophic Fe(II)-oxidizing prokaryotes utilize light as energy source and oxidize Fe(II) exclusively for assimilative purposes. The assimilative oxidation of Fe(II) leads to the formation of Fe(III) which is barely soluble at neutral pH. Neutrophilic phototrophic Fe(II)-oxidizing bacteria therefore have to cope with a virtually insoluble metabolic end product.

Anaerobic phototrophic Fe(II) oxidation

Anoxygenic phototrophic bacteria were the first prokaryotes discovered that oxidize Fe(II) in the absence of

molecular oxygen (Widdel et al., 1993). So far, only few cultures of Fe(II)-oxidizing anoxygenic phototrophic bacteria were established either from freshwater or from marine sediments. They are affiliated with the purple sulfur (*Thiodictyon* sp. strain F4), the purple non-sulfur (e.g., *Rhodobacter* sp. strain SW2, *Rhodovulum robiginosum*), or the green sulfur bacteria (*Chlorobium ferrooxidans*). All strains have the ability to utilize alternative electron donors such as hydrogen, reduced sulfur compounds, or organic acids (Canfield et al., 2005). The discovery of anoxygenic phototrophic bacteria that directly catalyze the oxidation of Fe(II), provides an alternative or additional explanation for the origin of Precambrian banded iron formations (Widdel et al., 1993; Kappler and Straub, 2005).

Summary

Phylogenetically diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to oxidize Fe(II) during aerobic or anaerobic respiration and/or for assimilative reduction reactions. Only one electron can be obtained from the oxidation of Fe(II) to Fe(III) and Fe(II)-oxidizing prokaryotes have to oxidize large quantities of Fe(II) to sustain cell metabolism. Due to the complex geochemistry of iron, acidophilic and neutrophilic Fe(II)-oxidizing prokaryotes have to cope with different constraints: (1) Acidophilic Fe(II)-oxidizing prokaryotes gain less energy in respiration than their neutrophilic counterparts; (2) Neutrophilic Fe(II)-oxidizing prokaryotes have to cope with a virtually insoluble metabolic end product. It is discussed that anoxygenic phototrophic Fe(II)-oxidizing bacteria contributed to the generation of Precambrian banded iron formations.

Definition

Fe(III)-reducing prokaryotes. Various species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to reduce Fe(III), ferric iron, to Fe(II), ferrous iron, by the transfer of electrons. The electrons for Fe(III) reduction derive mainly from the metabolic oxidation of organic compounds or hydrogen.

Introduction

Reduction of Fe(III) by prokaryotes has been known since the beginning of the twentieth century but was not considered to be of importance. At that time, only few bacterial strains were known to reduce small amounts of Fe(III) during fermentation. In addition, it was misleadingly presumed that prokaryotes cause reduction of Fe(III) mainly indirectly by producing sulfide, releasing organic compounds, lowering the redox potential, or decreasing the pH. This perspective changed notably with the discovery of dissimilatory Fe(III)-reducing bacteria, i.e., bacteria that utilize Fe(III) as terminal electron acceptor in an anaerobic type of respiration (Balashova and Zavarzin, 1979, 1980; Lovley and Phillips, 1988; Myers and Nealson, 1988). In order to gain energy for maintenance and growth by this type of respiration, significant amounts of ferric iron have to be reduced. Additionally, it became clear that neither lowering the redox potential nor decreasing the pH is sufficient to cause Fe(III) reduction. Furthermore, it was demonstrated that only very few organic compounds (e.g., fructose, cysteine) were able to reduce Fe(III) chemically at significant rates. In the last 20 years, numerous dissimilatory Fe(III)-reducing prokaryotes were identified and it is now generally accepted that this physiological group of prokaryotes has a strong influence on the iron geochemistry of most environments. Because many Fe(III)-reducing prokaryotes also have the ability to catalyze the reduction of Mn(IV) or Mn(III) to Mn(II) they additionally influence the geochemistry of manganese (Lovley et al., 2004; Canfield et al., 2005; Kappler and Straub, 2005).

Evolutionary consideration

The ability to reduce Fe(III) occurs widely within the domains *Bacteria* and *Archaea*. Most known Fe(III)-reducing prokaryotes that grow by Fe(III) reduction belong to the phylum Proteobacteria with representatives in each of the five subdivisions *Alpha*- (e.g., *Acidiphilium rubrum*), *Beta*- (e.g., *Ferribacterium limneticum*), *Gamma*- (e.g., *Shewanella oneidensis*), *Delta*- (e.g., *Geobacter sulfurreducens*), and *Epsilonproteobacteria* (e.g., *Sulfurospirillum barnesii*). Several Gram-positive bacteria that belong to the phylum Firmicutes (e.g., *Thermoanaerobacter siderophilus*) and some separate bacterial lineages like *Geothrix fermentans* or *Geovibrio ferrireducens* also have the ability to reduce ferric iron (Lovley et al., 2004). Fe(III) reduction in the domain *Archaea* was discovered by testing pure cultures that had originally not been isolated with Fe(III): Representatives of the phyla Euryarchaeota (e.g., *Pyrococcus furiosus*) and Crenarchaeota (e.g., *Pyrobaculum islandicum*) showed reduction of ferric iron (Vargas et al., 1998). The great phylogenetic diversity of Fe(III)-reducing prokaryotes with representatives in all deeply branching phyla, along with iron isotope studies, supports the hypothesis that Fe(III) reduction was an early mode of energy metabolism. Further geochemical evidences

suggest that other major electron acceptors such as sulfate, nitrate, or molecular oxygen were not available on early Earth (Lovley et al., 2004; Canfield et al., 2005; Johnson et al., 2008).

Geochemical aspects of Fe(III)

Iron is the fourth most abundant element in the Earth's crust and Fe(III) minerals may account for a few percent dry weight of rocks, soils, and sediments. Hence, in most anoxic ecosystems Fe(III) minerals are the dominant electron acceptors for bacteria and archaea. Today, 16 different Fe(III) oxides, hydroxides, or oxide hydroxides are known and for simplicity they are often collectively termed Fe(III) oxides. They are all composed of Fe together with O and/or OH and differ in composition and crystal structure. Widespread Fe(III) oxides include ferrihydrite, goethite, hematite, lepidocrocite, and magnetite (Cornell and Schwertmann, 2003). In contrast to other electron acceptors such as oxygen, nitrate, or sulfate, Fe(III) oxides are poorly soluble at neutral pH. The solubility of Fe(III) oxides at neutral pH depends furthermore on the type of oxide, the degree of crystallinity and the crystal size, and may range from 10^{-9} M (e.g., ferrihydrite, low crystallinity, small crystals) to 10^{-18} M (e.g., goethite, high crystallinity, large crystals). At circumneutral pH, Fe(III)-reducing prokaryotes therefore have to cope with a virtually insoluble electron acceptor. With increasing acidity, the solubility of Fe(III) oxides increases and ferric iron is well soluble at pH values below 2.5 (Cornell and Schwertmann, 2003). Concomitant with the change in pH and Fe(III) oxide solubility, the redox potential of the transition between ferric and ferrous iron changes significantly. The redox potential of the redox pair $\text{Fe}^{3+}/\text{Fe}^{2+}$ is +770 mV only at acidic pH values. At neutral pH, with poorly crystalline Fe(III) oxides (ferrihydrite, lepidocrocite) as the oxidant, the redox potential ranges between +100 and -100 mV, while the redox potential of more crystalline Fe(III) oxides (goethite, hematite, magnetite) may be as low as -300 mV (Canfield et al., 2005; Straub et al., 2001). In respect of solubility and energetics, acidophilic and neutrophilic Fe(III)-reducing prokaryotes cope with entirely different substrates.

Reduction of Fe(III) by fermenting bacteria

The first Fe(III)-reducing prokaryotes that were studied in laboratory cultures belonged to the domain *Bacteria* and reduced only small amounts of Fe(III) during fermentative growth on organic substrates such as glucose or malate. This physiological group comprises of a variety of bacteria and includes anaerobes (e.g., *Clostridium pasteurianum*, *Vibrio* spp.), facultative anaerobes (e.g., *Escherichia coli*, *Paenibacillus polymyxa*), and aerotolerants (e.g., *Lactobacillus lactis*, *Lactococcus lactis*). Accordingly, Fe(III) reduction by fermenting bacteria was observed under both anoxic and oxic culture conditions. For fermenting bacteria, Fe(III) reduction is

only a minor pathway for electron disposal and research on this type of metabolism fell behind efforts to understand dissimilatory Fe(III) reduction. The mechanism(s) of electron transfer to Fe(III) during fermentation is unknown and it is also unclear whether this process yields energy for growth. Thermodynamic calculations suggest that Fe(III) reduction during fermentation results in a slightly greater energy yield than fermentation alone but experimental evidences are ambiguous (Lovley, 1991; Canfield et al., 2005). So far no representative of the domain *Archaea* was described to reduce Fe(III) during fermentative growth.

Dissimilatory Fe(III)-reducing prokaryotes

Dissimilatory Fe(III)-reducing prokaryotes utilize Fe(III) as terminal electron acceptor in anaerobic respiration, i.e., they gain energy by coupling the oxidation of an electron donor to the reduction of Fe(III). As in the reduction of Fe(III) to Fe(II) only one electron can be disposed, dissimilatory Fe(III)-reducing prokaryotes have to reduce large quantities of Fe(III) to gain enough energy for maintenance and growth. Numerous strains of phylogenetically dispersed, dissimilatory Fe(III)-reducing prokaryotes have been isolated into pure culture or have been detected by molecular techniques in a wide range of pristine or contaminated habitats, including freshwater and marine sediments, wetlands, soils, aquifers, the deep subsurface, deep subterranean thermal water, hydrothermal vents, and hot springs (Lovley et al., 2004). This widespread occurrence correlates well with the ubiquitous presence of Fe(III) minerals. Consistent with the great variety of ecosystems inhabited, pure cultures of Fe(III)-reducing prokaryotes show a wealth of physiological qualities in respect to oxygen concentration (strict or facultative anaerobes), temperature (growth reported between 4 and 121°C), pH (growth reported between pH 1 and 9), and salinity (freshwater and marine species). In addition, autotrophic growth with carbon dioxide as sole carbon source and fixation of molecular nitrogen was described for some species of Fe(III)-reducing prokaryotes. No prokaryote characterized so far, depends solely on Fe(III) as terminal electron acceptor for growth. In the absence of Fe(III), prokaryotes either grow by fermentation (e.g., *Thermotoga maritima*) or utilize alternative electron acceptors. Common alternative electron acceptors include oxygen (e.g., *Pantoea agglomerans*), nitrate (e.g., *Geobacter metallireducens*), manganese (e.g., *Deferribacter thermophilus*), reduced sulfur compounds (e.g., *Desulfuromusa kysingii*), and fumarate (e.g., *Desulfuromonas acetexigens*). Furthermore, some species transfer electrons to heavy metals (e.g., uranium, chromium), graphite electrodes, humic substances, or chlorinated compounds (e.g., tetrachloroethene, trichloroacetic acid). The vast majority of Fe(III)-reducing prokaryotes utilizes fermentation end products such as acetate, ethanol, or hydrogen as electrons donors. Only few prokaryotes are known to couple the dissimilatory reduction of Fe(III) to the oxidation of sugars (e.g., *Acidiphilium*

cryptum), amino acids (e.g., *Geothermobacter ehrlichii*), long-chain fatty acids (e.g., *Desulfuromonas palmitatis*), monoaromatic compounds (e.g., *Geobacter metallireducens*), or reduced inorganic sulfur compounds (e.g., *Acidithiobacillus ferrooxidans*).

Acidophilic Fe(III)-reducing bacteria

A variety of autotrophic and heterotrophic bacteria that thrive in environments of low pH (<3) can grow by dissimilatory Fe(III) reduction (Johnson, 2007). All known species are facultative anaerobes, and most of them synthesize cell compounds required for dissimilatory Fe(III) reduction only in the absence of oxygen. In contrast, some species of acidophilic Fe(III)-reducing bacteria (e.g., *Acidiphilium cryptum*) constitutively express all genes necessary for Fe(III) reduction (Johnson, 2007). This is surprising because the redox potential of the redox pair O_2/H_2O reaches values above +1,000 mV below a pH value of 3 (Appelo and Postma, 2007). Hence, cells gain more energy by aerobic respiration than by utilizing Fe(III) as terminal electron acceptor (redox potential of the redox pair Fe^{3+}/Fe^{2+} : +770 mV).

Several species of acidophilic Fe(III)-reducing bacteria (e.g., *Acidithiobacillus ferrooxidans*, *Sulfobacillus acidophilus*) also grow by oxidizing Fe(II) with molecular oxygen; such prokaryotes were shown to catalyze the cycling of iron in laboratory experiments (Johnson et al., 1993). So far no representative of the domain *Archaea* was described to grow by dissimilatory Fe(III) reduction at acidic pH values.

Neutrophilic Fe(III)-reducing prokaryotes

The majority of dissimilatory Fe(III)-reducing prokaryotes that were isolated and characterized thrives at circumneutral pH and has to cope with a poorly soluble electron acceptor under natural conditions. In addition, the redox potential of the redox pair Fe(III)/Fe(II) is much lower (+100 to –300 mV, depending on the type of ferric iron oxide) than the redox potential of the redox pair O_2/H_2O (+820 mV) relevant for aerobic respiration. Therefore, at neutral pH, Fe(III) is a less valuable electron acceptor in terms of energy generation than molecular oxygen. Similarly, prokaryotes gain more energy from the respiration with nitrate or manganese as terminal electron acceptors. Hence, respiratory Fe(III) reduction at neutral pH occurs only under anoxic conditions in the absence of more favorable electron acceptors (Canfield et al., 2005). In some studies on neutrophilic Fe(III)-reducing prokaryotes, only chelated forms of ferric iron such as Fe(III) citrate or Fe(III) NTA (nitrilotriacetate) were applied. Caution is necessary in the interpretation of results from such studies because chelated Fe(III) forms are soluble at circumneutral pH, have redox potentials that are higher than those of non-chelated Fe(III) minerals, and may react rather unspecifically with electron-releasing cell compounds (Straub et al., 2001).

Most research on the biochemistry of microbial Fe(III) reduction focuses on members of the genera *Shewanella*

and *Geobacter*, two genera with significant differences in their basic physiology. *Shewanella* species are facultative anaerobes that belong to the *Gammaproteobacteria*. They grow very well in nutrient-rich medium and oxidize lactate or pyruvate incompletely to acetate. In contrast, species of the genus *Geobacter* belong to the *Deltaproteobacteria* and most of them are described as anaerobes. The most common electron donors utilized by *Geobacter* species include acetate, ethanol, and hydrogen. Despite differences in basic physiological features, various *c*-type cytochromes play a significant role in intracellular electron transfer processes in both *Shewanella* and *Geobacter* species.

Mechanisms of prokaryotic Fe(III) reduction

Considering the phylogenetically widespread ability of prokaryotes to reduce Fe(III) and the great prokaryotic physiological diversity, it is not surprising that Fe(III)-reducing prokaryotes developed different strategies to cope with Fe(III) as electron acceptor. According to experimental observations, prokaryotes developed the following strategies to transfer electrons from the cell to the surface of Fe(III) minerals: (a) Physical contact between cell and mineral surfaces allows for direct delivery of electrons; an attachment of cells to Fe(III) minerals has been repeatedly reported and seems to be the prerequisite for the delivery of electrons to Fe(III) in some Fe(III)-reducing prokaryotes such as *Geobacter metallireducens*. (b) Iron chelators increase the solubility of ferric iron; some evidence indicates that *Shewanella algae* and *Geothrix fermentans* produce and release Fe(III) chelators specifically during growth with Fe(III) minerals. (c) Electron-shuttling compounds accomplish the transfer of electrons from the cell to the mineral; diffusible electron-shuttling compounds help to bridge the spatial distance between cells and ferric iron (Lovley et al., 2004; Kappler and Straub, 2005). Reduction of Fe(III) by electron shuttling compounds is of particular importance in natural habitats where prokaryotic cells and Fe(III) minerals are not evenly distributed and Fe(III) might not be directly/physically accessible for prokaryotic cells. Naturally occurring electron-shuttling compounds that were shown to sustain prokaryotic growth include humic substances (Lovley et al., 1996) and sulfur compounds (Straub and Schink, 2004). Note that prokaryotes which reduce Fe(III) only via naturally occurring electron-shuttling compounds are no Fe(III)-reducing prokaryotes in a strict sense as their actual electron acceptor is the shuttling molecule and not Fe(III).

Summary

Phylogenetically diverse species of the prokaryotic domains *Bacteria* and *Archaea* have the ability to reduce Fe(III) during fermentative or respiratory growth by the transfer of electrons. Fe(III)-reducing prokaryotes have been recovered or detected in a great variety of pristine or contaminated habitats, and their widespread occurrence correlates well with the ubiquitous presence of Fe(III) minerals. Only one electron can be disposed

by the reduction of Fe(III) to Fe(II) and hence Fe(III)-reducing prokaryotes have to reduce large quantities of Fe(III) to sustain cell metabolism. Due to the complex geochemistry of iron, acidophilic and neutrophilic Fe(III)-reducing prokaryotes have to cope with different iron species: Fe(III) minerals are soluble only below a pH value of 3. At circumneutral pH, Fe(III) is only poorly soluble and significantly less energy can be gained by Fe(III) respiration compared to aerobic respiration. However, Fe(III) is the dominant electron acceptor in many anoxic habitats and prokaryotes developed different strategies for its utilization.

FERMENTATION

Fermentation is a route of obtaining energy from the oxidation of organic substrates using an endogenous electron acceptor (usually an organic compound). The energy yield in fermenting systems is limited when compared to respiration. Nevertheless, fermentation still allows growth under conditions when external, inorganic electron acceptors are lacking, or when iron as part of the electron carriers in the respiratory chain is not available and therefore an electron transport chain cannot be synthesized. Common fermentation substrates are sugars, which are present in large amounts in the environment, for example, as photosynthesis products and constituents of plant cell wall material. Microbial sugar fermentation pathways encompass lactic acid fermentation, alcoholic fermentation, and propionate fermentation, according to the major metabolic products generated. Another important fermentation pathway is acetoclastic methanogenesis, that is, fermentation of acetate to CO₂ and CH₄, which is performed by some methanogenic archaea (see entry “[Methane, Origin](#)”). [Hydrogen](#) is another common product of microbial fermentation processes.

Definition

FISH (fluorescence in situ hybridization) is a hybridization technique employing reverse complementary

fluorescently labeled probes to detect and localize only those parts of the chromosome, a gene or its transcript with which they show a high degree of sequence similarity. Results are mostly evaluated by either fluorescence microscopy or cell sorting methods like flow cytometry. Depending on target gene, probe chemistry, labeling, and combination with other analytical tools, a wide range of different FISH applications can be employed for advanced in situ analysis of community structure, dynamics, localization, activity, function and interactions of different cellular species.

Introduction

Antonie van Leeuwenhoek's ingenious improvement of the microscope in the seventeenth century revolutionized biology as this initiated novel ways to explore our world and ultimately led to the discovery of a new dimension of life forms, the microorganisms. However, since traditional microscopy reveals mainly structural features, its usefulness to advanced biological research reached its limits with the beginning of the molecular era. Fortunately, new possibilities for advanced microscopy applications emerged with the parallel development of two techniques: (1) in situ hybridization techniques (ISH) employing labeled gene probes targeting specific regions of a particular gene, and, (2) fluorescence microscopy. Fluorescence in situ hybridization (FISH) makes use of reverse complementary gene probes labeled with fluorochromes that are hybridized to specific regions on a chromosome (e.g., a specific gene) of gene transcripts (e.g., rRNA), and are then viewed by fluorescence microscopy or evaluated by other cell sorting methods like flow cytometry. FISH revolutionized nearly all disciplines in microbiology, in particular environmental research fields like microbial ecology, environmental biotechnology and geomicrobiology, since this enabled a cultivation-independent exploration of whole cells of culturable as well as not yet cultured microorganisms in their natural, complex environment (Amann et al., 1995; Amann and Fuchs, 2008). However, along with the development of other novel molecular tools and the growing comprehension of the enormous complexity of the biology of microorganisms, the first generation of FISH tools reached its limits as well, especially for applications on oligotrophic ecosystems characterized by a low amount of cells with often low activities in a strongly confounding background, which is often the case in geomicrobiology. Different modifications of the first generation FISH protocol as well as different combinations with other analytical tools were undertaken in order to meet the increasing demands with respect to, e.g., improved targeting of cells with low ribosome content or probe-repelling cell wall chemistry, alternative strategies to increase probe specificities or signal intensities, advanced image analysis, elucidation of activity and function by targeting other genes than the 16S rRNA gene and combining with different analytical tools, and finally cell enrichment of probe-targeted cells for,

e.g., subsequent identification by sequencing (Wagner et al., 2003; Wagner et al., 2006; Amann and Fuchs, 2008; Orphan, 2009; Wagner, 2009). The development of novel FISH protocols in combination with other advanced analytical tools and microscopes is most likely to continue to play a crucial role in microbial ecology and geomicrobiology research. Only microscopy-based tools can provide us with the possibility to visualize the morphotype, growth characteristics, spatial distribution, and interactions of different taxa on a single cell level within complex communities. Furthermore, despite all progress in nucleic acid-based approaches like PCR and the "omics" approaches, only microscopy-based tools can link isolated extracted DNA/RNA markers, with intact, individual cells in their natural environment, and thus also exclude molecular biases often observed with nucleic acid extraction and PCR (Table 1). The greatest benefit will be reached when combining different FISH tools with various methods such as cultivation and molecular approaches. Ultimately, a systematic approach can be undertaken to reveal discrepancies between different tools caused by extant biases of each tool in terms of sensitivity and specificity, so that a validated, advanced insight into the true diversity, dynamics, function, activities, and relationships in the microbial world can be obtained.

Sample preparation, fixation and storage of samples

In contrast to nucleic acid-based tools, which simply require either addition of preservative agents or instant freezing of biomass and storage in sterile tubes for subsequent nucleic acid extraction, preparation of samples for FISH requires usually more consideration and effort, especially for long-term storage of samples of unknown microbial composition and/or employing certain types of FISH protocols that may disrupt the original structure of the sample.

Preparations for standard applications

1. *Sampling strategy*: While FISH may principally work equally well on nearly any kind of optimally fixed cells with high ribosome content, irrespective of cell titers or the nature of the environmental sample, our abilities to detect, visualize, and quantify the cells may be obstructed by tedious, time-consuming screening of samples with either too low or too high cell counts, confounding background caused by autofluorescence of the background or unspecific binding of probes or labels to nontarget cells/substances (Amann and Schleifer, 2001). Some of these problems can be minimized by considering how the sample should be optimally treated already during sampling, for example, by concentration, dilution, embedding, cell extraction, or particular consideration on chemical-physical conditions to avoid cells getting exposed to stress.
2. *Fixation time and protocols*: The purpose of the fixation is to maintain the original microbial composition

Fluorescence In Situ Hybridization (FISH), Table 1 Advantages and disadvantages of FISH versus disruptive tools like PCR with ribosomal biomarkers

Diagnostic possibilities	PCR/qPCR/RT PCR	FISH ^a
<i>Experimental conditions:</i>		
Preparation of biomass prior to analysis	Nucleic acid extraction	Fixation of cells ^b
Long-term storage of sample	−80°/−20°C	−20°/+4°C ^b
Labor time (after NA extraction or fixation)	>6 h	0.5 h to 96 h
<i>Relevant parameters for microbial ecology:</i>		
Quantify distribution and dynamics	Yes/partly	Partly
Link targeted gene directly to cells	No	Yes
Visualize morphology and growth characteristics	No	Yes
Visualize associations with other microorganisms	No	Yes
Three-dimensional reconstruction of complex aggregates	No	Yes
<i>Methodological strengths/weaknesses:</i>		
Simultaneous identification of several genes	Only with multiplex PCR	Yes ^c
Distinguish gene targets in live/inactive/dead cells	No (for DNA)	Partly ^d
Distinguish false-positive gene products (chimera)	No	Yes
Quick check of cultures for purity	No	Yes
Enrich for subsequent analysis (e.g., sequencing)	Yes	Partly
Amplification biases	Yes	No ^e
Quantification bias caused by multiple ribosomal gene copies	Yes (for qPCR)	No
Bias caused by unspecific target binding	Possible	Possible
Biases caused by matrix	Inhibition	Autofluorescence
Detection limit	>5 gene copies	10 ^{5–7} cells/ml ^f

^aIncluding different FISH protocols and advanced microscopy tools.

^bIn certain cases, samples may be stored at −80°C and the fixation omitted (Yilmaz et al., 2010b).

^cOnly with certain FISH protocols like mRNA-CARD FISH, RING-FISH, gene-FISH, and in situ RCA.

^dDepends on the FISH protocol and how this is combined with other analytical tools and appropriate references.

^eException, FISH protocols based on PCR.

^fDepends on concentration/dilution procedure.

of the samples as well as the morphological integrity of cells during the different hybridization steps (elevated temperature, exposure to enzymes, detergents and osmotic gradients) and prevent cell losses, while simultaneously making the cells permeable for the probe(s) (Amann, 1995). Unfortunately, there is not one plain fixation protocol for all cell types for all different FISH protocols. Different fixation protocols have been developed to cope with the complexity of archaea, bacteria, and Eukarya with regard to their cell envelope packages and the type of probes to be employed for a particular FISH protocol. A suboptimal fixation protocol may make cells impermeable for probes or even cause cell lysis, especially during longer storage times or when exposing the cells to certain procedures such as incubation with enzymes prior to the FISH procedure. Apart from the selection of an optimal fixative reagent, it is also relevant to pay attention to the concentration of the fixative reagent and the incubation time and conditions. Fixation times may range from a few min up to >24 h, depending on cell type and FISH protocol, and are generally followed by a washing step for removal of the fixative reagent. The two most common fixation procedures are based on either aldehydes (e.g., formalin, paraformaldehyde (PFA), glutaraldehyde) or on alcohols (e.g., ethanol, methanol). In the

majority of cases, Gram-negative cells within the domain Bacteria are usually fixed with 4% PFA, and Gram-positive cells within the domain Bacteria with ice cold 96% ethanol (Amann, 1995). To a certain extent, some Gram-negative species will also tolerate EtOH fixation, and some Gram-positive species (general exceptions are, e.g., *Actinomycetes* and *Streptococci*) may also tolerate PFA fixation (especially if the incubation time is short, see, e.g., de los Reyes et al., 1997). The previously mentioned fixation protocols may also work well for certain Archaea and Eukarya species, but in some cases, especially for certain Archaea species (Nakamura et al., 2006) or eukaryotes like fungi (Baschien et al., 2001; Tsuchiya and Taga, 2001; Weber et al., 2007) or protozoa, see, e.g., Fried et al. (2002); Petroni et al. (2003); Fried and Foissner (2007); Weber et al. (2007), other fixative reagents or post treatments with enzymes like chitinase or endo-isopeptidase are more suitable. When dealing with unknown samples, it is therefore recommended to explore the suitability of different fixation protocols. Irrespective of the fixation protocol used, the cells must be fixed as soon as possible with optimally prepared fixation solutions, preferably already during the sampling occasion to avoid population shifts and for optimal evaluation of true probe signal intensities as these

may in certain cases also serve as an indicator of activity (see, e.g., Wagner et al., 1995; Molin and Givskov, 1999; Rossetti et al., 2007).

3. *Storage of fixed cells:* Fixed samples (in wet or dry state, such as on a microscope slide or on a membrane filter) can be stored at room temperature or at +4°C for shorter periods. For optimal long-term storage at -20°C, fixed cells are generally dissolved in a 1:1 (v/v) solution with a 50% end concentration of ethanol in order to avoid freezing (Amann et al., 1994). Cells concentrated on a membrane filter are normally stored dry at -20°C (e.g., Teira et al., 2004). So far, no systematic studies on the maintenance of cell integrity or ribosome content in fixed cells after longer storage periods exist, but it is generally recommended that once the cells have been fixed, quantitative studies should be performed within days to avoid biases caused by unknown deterioration of cells or decrease of ribosome content.

Preparations for omics-based applications

For genomic or proteomic applications, unfixed biomass is desirable to minimize possible sequencing biases introduced by cross-linking and to avoid possible cell lysis difficulties, so that FISH targeted cells can be enriched by, e.g., flow cytometry and subjected to, e.g., whole genome application. Recently, Yilmaz et al. (2010b) demonstrated that the standard oligonucleotide FISH protocol can also be performed on at least two different types of frozen, non-fixed complex environmental samples using Archaea as well as Bacteria targeted probes. However, more research is needed to explore further possibilities as well as limits of this approach, such as if this is quantitative and if this applies to any kind of cells types or other environmental samples, irrespective of growth and storage conditions, as well as if this approach is also suitable for other types of FISH protocols.

FISH for in situ detection of ribosomal genes

General background: The ribosomal gene was and will at least for the near future remain the standard gene for reconstruction of phylogeny, despite the growing amount of genome sequences which is presently revolutionizing our current concepts of taxonomy, phylogeny, and development of comprehensive biomarkers for improved identification (see, e.g., Konstantinidis et al., 2009). The main benefits of the ribosomal gene is that it is a functionally conserved molecule present in high numbers in all organisms from all domains and is composed of sequence regions of higher and lower evolutionary conservation. The variable conservation degree makes it particularly ideal for design of biomarkers for nucleic acid-based detection and quantification of different levels of microbial diversity (Ludwig et al., 1998; Priesse et al., 2007; Amaral-Zettler et al., 2008; Yarla et al., 2008). Although several different types of ribosomal subunits exist, only a few of these are currently used as targets for probes in

FISH studies. For most FISH studies, the main gene target is the 16S rRNA gene for prokaryotes, and the 18S-rRNA gene for eukaryotes (Ludwig et al., 1998; Metfies et al., 2008). However, other multicopy ribosomal genes or even stable multicopy RNA molecules have been (5S-rRNA, tmRNA), or may be occasionally used as alternative targets for FISH probes (23S-rRNA, 28S-rRNA, precursor rRNA, intergenic spacer region). These alternative gene targets may overcome some of the problems occasionally encountered when targeting the 16S rRNA gene, such as low information content and limited probe accessibility or information about activity status (Trebesius et al., 1994; Oerther et al., 2000; Schmid et al., 2001; Schonhuber et al., 2001; Zimmermann et al., 2001; Peplies et al., 2004). However, despite this, the 16S rRNA gene has remained the main gene target in FISH applications, especially for environmental systems with unknown diversity, since the 16S rRNA gene is nowadays routinely sequenced in most studies so that the amount of retrieved 16S rRNA gene sequences has thus come to outrange all other databases of other gene sequences.

Principle of FISH: The FISH procedure generally consists of the following steps (Adapted from Manz et al., 1992 and Amann, 1995):

1. Optional: For certain cases an additional post-treatment of the fixed/non-fixed biomass may be needed for increased permeabilization of probes through rigid cell envelope packages, or for removal of confounding background, by, e.g.:
 - Incubation with enzymes like lysozyme, protease, proteinase K, mutanolysine, endoisopeptidase, chitinase
 - Removal of wax or chemical precipitates by chemical solvents
 - Use of detergents (SDS) or other chemicals like hydrochloric acid
 - Physical treatment like exposure to microwave radiation
 - Addition of chemicals to avoid dissolution of essential compounds
2. Successive dehydration in an EtOH series (50%, 80%, 96%, each step between 1–3 min).
3. Hybridization of the fixed sample with the probe on a microscope slide or in solution under stringent conditions (Figure 1). Stringent conditions are achieved by keeping the hybridization temperature constant (+46°C) but varying the formamide concentration for different probes (Stahl and Amann, 2001).
4. Subsequent washing with preheated buffered washing solutions at a slightly higher temperature (+48°). After this, the hybridized samples can be evaluated or stored at dark prior to evaluation (for a shorter period at room temperature or at +4°, for longer periods, at -20°C).
5. Optional: Counter stain with, e.g., an appropriate nucleic acid stain like DAPI (4',6-diamidino-2-phenylindole) or SYBR Green (e.g., Wagner et al., 1994, or Engel et al., 2003).

Fluorescence In Situ Hybridization (FISH), Figure 1 (a) Schematic outline of the standard oligonucleotide FISH procedure on microscope slides. (b) Schematic outline of a cell before and after the standard oligonucleotide FISH procedure.

6. Evaluation is achieved by:

Visualization:

- Standard epifluorescence microscopy, or confocal laser scanning microscope for three-dimensional reconstruction (Wagner et al., 1998).
- Combination with other microscopes like electron microscopy (e.g., Gerard et al., 2005), RAMAN spectroscopy combined with a microscope (Wagner, 2009), or nanoSIMS (Behrens et al., 2008; Orphan, 2009).

For digital image analysis of FISH images, various software packages are available, such as CMEIAS, COMSTAT, and daime (Heydorn et al., 2000; Daims and Wagner, 2007; Zhou et al., 2007; Daims, 2009).

Other options:

- Membrane-based evaluation (e.g., dot blot, Wagner et al., 1994).
- Combination with other analytical tools (e.g., screening of uptake of radioactive tracers or stable isotopes

(Nielsen et al., 2005; Orphan, 2009) or other FISH protocols targeting non-ribosomal genes or their transcripts for exploring activities or functions.

- Reverse hybridization by microarray technology, where multiple probes are deposited on a support material to hybridize a labeled sample with the probes (DeSantis et al., 2005; Loy and Bodrossy, 2006; Taylor et al., 2010).
- Cell sorting or probe signal intensity evaluation by flow cytometry (Behrens, 2003; Amann and Fuchs, 2008), RING (Recognition of Individual Genes)-FISH (Zwirgmaier et al., 2004b), or magneto-FISH (Orphan, 2009).
- Whole genome amplification (Orphan, 2009; Yilmaz et al., 2010b).

Basic equipment and reagents for standard FISH applications:

- Hybridization oven (46°C)
- Water bath (48°C)
- Polypropylene screw top tubes, filter paper

- Reagents (for chemical composition, check, e.g., Amann, 1995):
 - NaCl
 - Tris/Phosphate buffer
 - EDTA
 - SDS
 - Formamide
 - 50%, 80%, 96% EtOH
 - Reagents/equipment for improved probe accessibility
- Labeled probes
- Counterstains like nucleic acid stains (e.g., DAPI (4',6-diamidino-2-phenylindole) or SYBR Green)
- Microscope slides (possibly coated with, e.g., poly-L-lysine (Sigma-Aldrich, www.sigmaaldrich.com/sigmaaldrich/home.html) or a gelatine-chromium sulphate solution (Amann, 1995))
- Mounting medium of appropriate pH (e.g., from Citifluor, www.citifluor.co.uk/; Vectashield, www.vectorlabs.com/; various mounting media from Invitrogen, www.invitrogen.com/site/us/en/home.html)
- Some form of fluorescence microscope.

FISH probes (probe design, probe evaluation, probe databases)

For a proper interpretation of FISH experiments, probes need to be optimally designed and handled. Several different types of softwares (e.g., the ARB software package, (www.arb-home.de/) and Primrose (www.bioinformatics-toolkit.org/index.html)) and detailed guidelines for probe design for particularly FISH experiments exist (Amann, 1995; Amann and Schleifer, 2001; Stahl and Amann, 2001), and (Hugenholtz et al., 2001). Below follows an updated summary of some of those guidelines, focusing mainly on applications with the ARB software package:

1. Construction of a molecular data base: Prior to all probe design, a comprehensive data base of all relevant complete gene sequences of the target group and relevant nontarget groups should be collected for a thorough evaluation of phylogenetic relationships. Partial sequences may also be included, but these should be handled more critically due to their limited value for a full evaluation of all potential probe targets. Sequences can be downloaded from different categories of databases: (1) all kinds of gene sequences: EMBL (www.embl.de/), NCBI (www.ncbi.nlm.nih.gov/), (2) regularly updated and curated ribosomal gene sequences: RDP (<http://rdp.cme.msu.edu/>), SILVA (www.arb-silva.de/), Green Genes (<http://greengenes.lbl.gov/cgi-bin/nph-index.cgi>); the ribosomal internal spacer collection (<http://egg.umh.es/rissc/>); (3) functional genes: Fun Gene (<http://fungene.cme.msu.edu/index.spr>). Principally, most softwares that can align sequences, perform phylogenetic evaluations, and design biomarkers like PCR primers can be used for FISH probe design as well.

However, the bioinformatic software package ARB (www.arb-home.de/) using the curated SILVA database (www.arb-silva.de/) is highly recommended, as several useful and partly unique tools have been implemented into this package to facilitate a straightforward and advanced design, evaluation and visualization of probes and their target (Ludwig et al., 2004; Kumar et al., 2005; Kumar et al., 2006; Priesse et al., 2007).

2. Hierarchic probe design strategy: Where possible, it is recommended to design a hierarchic probe set consisting of several probes targeting different phylogenetic levels of the target organism/group (see, e.g., Amann and Schleifer, 2001; Amann and Fuchs, 2008). If the different probes are labeled with different fluorochromes and combined in one FISH experiment on a mixture of cells with different phylogenetic relationships, different overlaps of the probes will produce different color combinations depending on the taxonomical relationships. This facilitates a straightforward top to bottom identification of the taxonomical status (e.g., from phylum down to species level) of different cell species in a complex sample (Amann, 1996).
3. General rules for standard oligonucleotide probe design:
 - (a) Select the appropriate gene sequences of the desired target group. Depending on bioinformatic software, design the probe according to the recommended procedure. For example, if using the ARB software (Ludwig et al., 2004), select from the menu "probe design" an appropriate PT server, then define appropriate parameters such as length of probe (average length of probes for standard oligonucleotide probes is between 15–25 nucleotides), minimum group and maximum non-group hits, GC content, melting temperature range, range of nucleotide positions, and maximum hair-pin bonds.
 - (b) The selected probe should be completely specific (complementary) to a region of the selected target sequences and have at least one mismatch to the same target region in nontarget sequences. Optimally, the mismatch should be centralized in the nontarget sequences in order to maximize the destabilizing effect of the mismatch.
 - (c) Perform probe match to evaluate the specificity of the probe (e.g., in the bioinformatic software package ARB (www.arb-home.de/), the RDP Probe Match tool (<http://rdp.cme.msu.edu/probematch/search.jsp>), the probeBase probeCheck tool (<http://131.130.66.200/cgi-bin/probecheck/content.pl?id=home>) or general data bases like the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov/).
 - (d) Unfortunately, there is no such thing as a perfect probe that only targets the target group as the course of the evolution of gene sequences is a random process. During a recent review Amann and Fuchs (2008) showed that it is more advisable to

evaluate group coverages as the percentage of group members that can be identified relative to the total number of members in the target group. With this approach, three groups can be distinguished: true positives; false negatives; and false positives. Parallel to the constantly growing amount of gene sequences, the coverage of each probe target group is ultimately going to change and possibly demand more complex probe sets. For example, in the early days of the FISH technology, only one probe was needed to target all recognized species in the Bacteria domain (Amann et al., 1990). However, a decade later, Daims et al. (1999) showed that a mixture of three different Bacteria domain targeting probes were needed to cover all so far (up till 1999) recognized sublineages.

- (e) Evaluate the melting temperature of the probes (e.g., as described by (Hugenholtz et al., 2001) or the probeBase, www.microbial-ecology.net/probebase/). Optimally, the probe should have a melting temperature $> 57^{\circ}\text{C}$. If the melting temperature is $< 57^{\circ}\text{C}$, the temperature can be increased by shifting the position of the probe or expanding the length of the probe.
 - (f) Check probe accessibility. A reoccurring problem is the probe accessibility. The general explanation for is that certain regions of the secondary structure of the ribosomal gene are inaccessible for probes. Unfortunately, the accessible and inaccessible regions of the ribosomal molecules appear to vary from species to species, so that only precise estimations of probe accessibilities can be made for those species where a systematic probe accessibility mapping has been performed (see, e.g., Fuchs et al., 1998; Behrens, 2003a, 2006b). The general recommendation is therefore to design probes on different target positions and then to simply explore on a trial-and-error experimental basis which of the selected probes produce high probe signals. However, Yilmaz et al. (2006) showed that principally all positions on the ribosome molecule may yield satisfying probe signals if a sophisticated approach based on a thermodynamics-based probe design is employed. With this approach, FISH experiments of any given probe can be mathematically simulated. Based on this, theoretical predictions on, e.g., the probe accessibility, the formamide denaturation profile, and the potential of mismatch discriminations can be made (for further details see Yilmaz et al., 2010a). Based on this, further optimizations of the probe accessibility can be made such as modifying the length of the probe or the experimental hybridization conditions (e.g., increase of the hybridization time up to 96 h).
 - (g) Check for potential self-complementarity of the probe which may initiate duplex formations between the probe and the target (e.g., caused by hairpins or dimers).
 - (h) Naming of probe. There are three types of nomenclatures for probes: (1) the short name (e.g., EUB 338), which is often constructed by a shortage of the name of the target group (e.g., EUB for Eubacteria), followed by a number that denotes the first position of the probe on the target gene (e.g., nucleotide position 338 on the *E. coli* gene); (2) a name based on a comprehensive nomenclature to denote main features of the probe such as the target gene, target group, target group level, 3' end of the probe, and probe length (Alm et al., 1996); and (3) the probeBase accession number (e.g., pB-00159 for probe EUB 338) as assigned by the online probe database ProbeBase (www.microbial-ecology.net/probebase/).
4. Labeling of probes: The first rRNA-targeted oligonucleotide probes for FISH were radioactively labeled, developed by microautoradiography and evaluated by light microscopy (Giovannoni et al., 1988). Unfortunately, the work with radioactively labeled probes restricted the applicability of FISH. However, the applicability of FISH increased as soon as the first fluorescently labeled rRNA-targeted oligonucleotide probes were reported (DeLong et al., 1989). Probes are nowadays generally covalently labeled at the 5' end of the oligonucleotide, and the most commonly used fluorochromes for FISH are sulfoindocyanine fluorochromes like Cy3 and Cy5, fluorescein, ALEXA probes, rhodamine, and Texas red. The criteria for selecting appropriate fluorochromes are based on the capabilities of the available epifluorescence microscope and on the nature of the cells and their surrounding environment, where the aim is to avoid a confounding background and unspecific binding of fluorochromes to nontarget cells, and/or to minimize bleaching of probe signals. During the last decade, several different approaches have been used to increase the probe signal intensities in those cases where standard labeled probes produce too weak fluorescent signals. A simple strategy was to employ mixtures of mono-labeled probes targeting different sites of the ribosomal gene (e.g., Amann et al., 1990; Krumholz et al., 1990; Morris et al., 2002; Sunamura and Maruyama, 2006). Another strategy is to employ alternative labeling procedures of oligonucleotide probes, such as polynucleotide FISH (e.g., Trebesius et al., 1994), horseradish peroxidase (employed in catalyzed reporter deposition (CARD-FISH), e.g., Pernthaler et al., 2002a; Wendeberg, 2010) or various types of multiple labeling of probes (Amann and Schleifer, 2001) such as DOPE-FISH (Stoecker et al., 2010).
 5. Purchase and handling of probes: Probes are chemically synthesized and can be purchased with or without label. In earlier times, probes had to be manually labeled (Amann, 1995), but nowadays labeled probes can be easily purchased from most providers (e.g., Biomer, Invitrogen, MWG, SIGMA) of molecular reagents like PCR primers at a rather low cost (starting

from approximately 50 USD). Probes are normally shipped in lyophilized stage and must be dissolved in either sterile water or an appropriate buffer (depending fluorochrome chemistry) to a stock solution of normally 100 pmol/μl. It is recommended to store aliquots of working solutions in individual tubes in dark at -20°C, and to avoid excessive freeze-thawing of the aliquots. For long time storage or transport at room temperature it is recommended to lyophilize the probes.

6. Evaluation of probes:

(a) For any purchased probe, it is recommended to check for the probe's concentration, length, homogeneity, and the completeness of the labeling, to avoid unwanted competition between labeled and unlabeled probes for target sites as this may reduce the probe signal intensity. This can be done as described by Stahl and Amann (2001), or as recommended by the provider who performed the labeling.

(b) Newly designed probes are generally first tested under non-stringent conditions (i.e., by excluding formamide in the hybridization buffer). If positive probe signals are obtained in reference strains as expected, stringent conditions of the probe should be determined by an increasing formamide series, as described in Amann and Schleifer (2001). Probe signal intensities can be quantified by digital image analysis with, e.g., the daime software, as described by (Daims et al., 2009).

(c) Combination of probes. The great advantage of FISH over standard PCR applications is that several differently labeled gene probes can be simultaneously combined and thus enable a simultaneous identification of different probe-targeted species within a complex sample. The general guidelines for optimal combination of different probes are:

- Probes with identical formamide concentrations for optimal stringencies (at which the probe hybridizes to the specific target but not to nontarget groups) can be combined in the same hybridization experiment.
- Probes with different formamide concentrations for optimal stringencies cannot be combined in the same hybridization experiment. Instead, successive hybridizations must be performed for each probe, starting with the probe with the highest formamide concentration.

(d) Most standard epifluorescence microscopes are equipped with filter sets that allow separate recording of at least two to three differently labeled probes and one UV-based nucleic acid stain like DAPI (4',6-Diamidino-2-phenylindol). Such recorded images can then be merged into one image with image analysis software packages. However, recent developments based on, e.g., advanced confocal laser scanning microscopes with multichannel image analysis, special tools such as spectral imaging or FISH protocols employing quantum dot

labeled probes allow the simultaneous combination of a considerably higher amount of differently labeled probes (e.g., Ainsworth et al., 2006; Anderson, 2010; Bentolila et al., 2006).

7. Probe bases: Different attempts to construct databases with FISH probes have been made during the last two decades. However, the probeBase (www.microbial-ecology.net/probebase/) is currently the most regularly updated data base for ribosomal targeted probes, encompassing 2,568 different probes targeting species within Archaea, Bacteria, and, to some extent, Eukarya (further probes targeting protists and cyanobacteria can be retrieved from www.sb-roscoff.fr/Phyto/Data-bases/RNA_probes_introduction.php) for FISH as well as for ~16 different microarray applications (version September 2010). Here, many of the so far published probes can be easily searched by different criteria (target organism, target sites, probe name, probe sequence, probeBase accession number, references). Detailed information about the probe chemistry are listed and links are provided for online probe matches to other databases like the ProbeCheck (<http://131.130.66.200/cgi-bin/probecheck/content.pl?id=home>), Green Genes (<http://greengenes.lbl.gov/cgi-bin/nph-index.cgi>), or RDP (<http://rdp.cme.msu.edu/>). Furthermore, up to 150 ribosomal gene sequences retrieved from own clone libraries can be uploaded to screen for probes targeting these sequences (Loy et al., 2007, 2008).

8. Controls: For a valid evaluation of probe signals, three different categories of controls are needed: (1) Positive controls where probes are employed that should or should not overlap with the intended target gene. (2) Negative controls, to explore the impact of confounding background caused by, e.g., autofluorescence, and of nonspecific binding of fluorochrome or probe to target cells as well as nontarget cells. To achieve this, two different negative controls are recommended: exclusion of probes during the hybridization experiment, and application of negative reference probes like the NON-SENSE probe (Loy et al., 2002) or the non-EUB probe (reverse complementary to the EUB probe, (Wallner et al., 1993)). (3) All experiments should be performed on appropriate optimally fixed strains carefully selected to serve as positive as well as negative controls.

9. Other probe types: Note that some of the rules applied for design and handling of standard oligonucleotide probes may not be applicable to other probe types, like polynucleotide probes, PNA FISH probes, or CARD FISH probes.

General guidelines for evaluation and presentation of FISH results

For optimal interpretation of FISH experiments, several parameters should be considered, as outlined below. Omitting any of these principles may lead to false interpretations of FISH results.

Checklist for optimal FISH experiments and evaluation of results:

1. Were optimal sampling strategies, fixation protocols, and storage conditions employed?
2. Were appropriate reference strains used simultaneously in parallel with the FISH experiments? If strains are lacking, clones based on CLONE-FISH (Schramm et al., 2002) may also be used to experimentally evaluate the FISH experiments.
3. Were the microscopical investigations performed with optimal microscope settings?
4. Were appropriate probes/probe combinations (positive as well as negative controls) used under stringent conditions?
 - (a) If the probe signals were positive, explore if nonspecific probe signals can be unequivocally excluded or if the identity of the probe signal can be confirmed with other measures.
 - (b) If the probe signals were negative on the sample subject to investigation but otherwise positive with positive controls, explore if this is caused either by cell losses during the hybridization procedure, low cell numbers in the original sample, or low activity (and thus low ribosome content and probe signal intensity).
5. If quantifications of FISH images were performed, explore if the amount of sample applied to the microscope slide was appropriate. A too high or too low cell concentration may result in an over- or underestimation of cell numbers. Evaluate also if the amount of microscope slide fields investigated was high enough to ensure statistical evaluations of error ranges. For further evaluation of quantification, spiking of sample may be recommendable (SPIKE-FISH, Daims et al., 2001).
6. When presenting FISH results, it is recommended to describe results as "cells targeted by probe X," instead of uncritically identifying the probe signals with the intended target group of the probe. This is especially important when applying probes to samples with unknown microbial composition and the applied probe is known to target false-positive as well as false-negative species and no further means have been undertaken to confirm the identity by, e.g., appropriate combinations of hierarchic FISH probe sets or subsequent sequencing (Amann and Fuchs, 2008).
2. Confounding background caused by auto-fluorescing compounds like photosynthetic pigments, proteins like cofactors (e.g., F420 for methanogens), other parameters in the surrounding environment (e.g., precipitates, fibers, minerals, humic substances); or by unspecific absorption of fluorochrome label.
3. Probe technical problems (e.g., probe permeabilization problems, probe accessibility in the ribosomal gene, probe specificity).
4. Limited information content of the 16S rRNA gene for taxonomical resolution of closely related species.
5. Limited possibilities to confirm true identity and explore phylogenetic relationships and identify novel gene groups or species.
6. Limited information on in situ physiology in terms of:
 - (a) Activity status (high ribosome content may reflect exponential growth stage, but this appears to be species dependent and needs to be explored for each particular species group (Wagner et al., 1995; Molin and Givskov, 1999; Rossetti et al., 2007);
 - (b) Function, since the ribosomal gene does not reveal information about function and since the genotype is not always linked to the phenotype (e.g., many functional microbial groups are polyphyletic, such as methanogens, sulphate reducers, denitrifiers, cyanobacteria, spirochaetes, reductive dechlorinators);
 - (c) Limited possibilities to monitor gene expressions (mRNA transcripts) or proteins.
7. Applications limited to prokaryotic and eukaryotic cells. However, the first notes on successful FISH applications on bacteriophages (personal communication, K. Zwirgmaier, D. Scanlan, A. Millard, University of Warwick, UK) was recently made with the Recognition of individual genes [RING]-FISH protocol (Zwirgmaier et al., 2004b).

To overcome these limitations, several different strategies have been employed, ranging from modifying different parts of the procedures of the first-generation FISH protocol, searching for alternative gene targets, probe chemistries and labeling procedures, to combining FISH with other markers (e.g., activity stains, enzymes, isotopes), analytical procedures, and advanced microscopes or other analytical tools for evaluation of several different parameters for a holistic interpretation of in situ microbial ecology. Today, at least four categories of advanced FISH strategies can be recognized, which can be combined in a multitude of ways for various novel applications.

Category I – increasing the probe signal intensity:

Drawbacks of oligonucleotide FISH and the benefits of novel FISH technologies

The first generation of FISH protocol based on oligonucleotide probes revolutionized nearly all disciplines in microbiology. However, along with applications of this protocol on different ecosystems and species, many of the limits of the first-generation FISH protocol became obvious:

1. Successful detection dependent on ribosome content (minimum 370 ± 16 rRNA molecules per *E. coli* cell (Hoshino et al., 2008)).

- Incubate sample prior to fixation with substrates or stress-promoting compounds like chloramphenicol (Kalmbach et al., 1997; Ouverney et al., 1997).
- Employ non-fluorescent labeling of probes for increased detection of cells in, e.g., a strongly autofluorescing background based on, e.g., radiolabels (Giovannoni

et al., 1988); or enzymes (Zarda et al., 1991; Amann et al., 1992; Lim et al., 1993).

- Employ alternative probe design based on helper probes for oligonucleotide probes to increase probe accessibility (Fuchs, 2000).
- Employ alternative probe chemistries for increased hybridization efficiencies and specificities based on peptide nucleic acid probes (PNA) (Perry-O'Keefe et al., 2001), or locked nucleic acid (LNA) probes (Kubota et al., 2006a).
- Explore probe accessibilities and thermodynamics-based probe design to predict probe accessibilities and optimal hybridization conditions (Yilmaz et al., 2006; Yilmaz et al., 2010a), and/or in nucleotide or probe quenching (Behrens, 2003; Behrens et al., 2004; Wagner et al., 2003).
- Employ self-ligating probes to overcome background autofluorescence and avoid washing steps (Sando and Kool, 2002).
- Employ PCR-generated probes to generate polynucleotide probes (Trebesius et al., 1994; Zimmermann et al., 2001; Meisinger et al., 2007; Pernthaler, 2002; Preston et al., 2002; Moraru et al., 2010).
- Employ modified fluorescent labeling technologies based on horse radish peroxidase labeled probes and catalyzed reporter deposition (CARD)-FISH (Pernthaler et al., 2002a, b; Hoshino et al., 2008; Pavlekovic et al., 2009); multiple labeling of probes (Amann and Schleifer, 2001; Stoecker et al., 2010) or quantum dot conjugated probes (Bentolila et al., 2006).

Category II – exploring activity or function:

- Combine FISH with rRNA dot slot to quantify cellular rRNA content (Ravenschlag et al., 2000).
- Employ FISH probes targeting the precursor 16S rRNA gene and intergenic spacer regions (Oerther et al., 2000; Schmid et al., 2001; Moter et al., 2010).
- Combine FISH with different activity indicating stains like redox dyes (Nielsen et al., 2003), halogenated thymidine analogue bromodeoxyuridine (BrdU) (Pernthaler et al., 2002), exo-enzyme labeled probes (Xia et al., 2007), or antibodies to target cell surface markers or proteins (Currin et al., 1990; Lubeck et al., 2000; Gmür and Lüthi-Schaller, 2007).
- Incubate sample with radioactively labeled substrates or stable isotopes to explore specific uptake of labeled substrates by micro-autoradiography (Nielsen et al., 2005), RAMAN spectroscopy (Wagner, 2009), or nano-SIMS (Behrens et al., 2008; Orphan, 2009).
- Target functional genes or even the mRNA gene by CARD-FISH (Wagner et al., 1998; Pernthaler and Amann, 2004; Orphan, 2009; Pilhofer et al., 2009), two-pass TSA-mRNA FISH (Kubota et al., 2006b), or by alternative labeling (Coleman et al., 2007).
- Target functional genes. For this, there are two categories: (1) PCR-generated probes like polynucleotide

FISH (Moraru et al., 2010) or (2) amplification of the target sequence like in situ PCR (Hodson et al., 1995; Rodríguez-Castaño, G., 2008; Tani et al., 1998), in situ loop-mediated isothermal amplification (Maruyama et al., 2003); recognition of individual genes [RING]-FISH (Zwirgmaier et al., 2004b; Pratscher et al., 2009; Hauer et al., in preparation), in situ rolling-circle amplification (Maruyama et al., 2005; Hoshino et al., 2010), cycling primed in situ amplification (CPRINS, Kenzaka, 2005; Tamaki et al., 2005), circularizable probes (Zhang et al., 2006), circularizable probes (Zhang et al., 2006; Hoshino et al., 2010), peptide nucleic acid assisted rolling circle amplification FISH (Smolina et al., 2007), and polynucleotide FISH (Moraru et al., 2010).

Category III – combining FISH with advanced cameras, microscopes, or other analytical tools:

- CCD camera (Amann and Schleifer, 2001); confocal laser scanning microscopy (Wagner et al., 1998), and advanced digital image processing (Daims, 2009; Daims and Wagner, 2007)
- Electron microscopy (Kenzaka et al., 2005; Ishidoshiro et al., 2005)
- Spectral imaging (Ainsworth et al., 2006)
- RAMAN spectroscopy (Wagner, 2009)
- nanoSIMS (Behrens et al., 2008; Orphan, 2009)
- Atomic force microscopy (Huang et al., 2009)

Category IV – enrichment of FISH targeted cells for subsequent analyses, and combination with high-throughput technologies:

- Automatic cell sorting and enrichment techniques based on flow cytometry (Amann and Fuchs, 2008)
- Magneto-FISH (Orphan, 2009; Stoffels et al., 1999)
- RING-FISH (Zwirgmaier et al., 2004a)
- Whole genome amplification (Yilmaz et al., 2010b)

Many of these improvements minimize at least some of the drawbacks observed with the first generation FISH protocol; however, these new approaches do also introduce other drawbacks. For example, CARD-FISH has replaced the standard FISH protocol in several cases because it produces stronger probe signals (Pernthaler et al., 2002a, b) and just recently it was shown that it can be combined with polynucleotide probes targeting functional genes in a subsequent step (Moraru et al., 2010). Nevertheless, compared to standard oligonucleotide FISH, CARD-FISH is a rather time-consuming FISH protocol and allows only the application of one probe per hybridization experiment. Furthermore, as peroxidase can be found in nearly all organisms, there may be a risk for unspecific probe reactions. Fortunately, the peroxidase can be denatured prior to the FISH procedure, however, optimal denaturation conditions appear to be species dependent and may thus require individual optimizations (Pavlekovic et al., 2009). Similarly, the recent developments of various protocols to target non-ribosomal genes

like various functional genes and mRNA transcripts, or combining with various analytical tools, present different advantages as well as disadvantages. For example, considerable higher costs, advanced equipment, tedious protocols, loss of probe specificity, less flexibility in terms of combination with other probes or protocols or on various organisms, problems with adequate preservation of gene target due to high decay rate (e.g., precursors or mRNA), or unpredictable cross-reactions (e.g., when incubating a complex community with radioactive substrates or stable isotopes). However, irrespective of these drawbacks that may eventually be overcome in future, it is crucial to keep in mind that our greatest hindrance for successful, unequivocal interpretations of FISH experiments in the environment is the unknown biodiversity and multitude facets of dynamics and interactions, which paradoxically seem to grow with each advancement in the science of microbiology. Thus, it appears likely that the development of novel FISH technologies will continue in parallel with the development of novel tools and our increased understanding of microbial diversity.

Different FISH applications in geomicrobiology

The fields explored in geomicrobiology are extremely diverse, ranging from the deep biosphere to the atmosphere surrounding our planet Earth, and from there to the outer space. The conditions for the different ecosystems will therefore vary tremendously so that different sampling technologies and modifications of FISH protocols must be employed in order to achieve successful FISH results. So far, FISH has not been employed in geomicrobiology as often and as successfully as in other microbiological fields like environmental biotechnology (e.g., wastewater treatment plants, Nielsen et al., 2009) or in medical sciences (e.g., Bridger et al., 2010). This is because many of the ecosystems explored in geomicrobiology are often exposed to extreme conditions and generally contain low amounts of usually novel microorganisms with slow or unknown growth rates. Furthermore, special considerations must be made in terms of interpreting results with regard to the risk of contamination of samples during sampling (e.g., during drilling experiments) and to the impact of geochemical conditions on so far published FISH protocols. Because of these obstacles, many of the recent advanced developments of FISH protocols have actually been driven by microbial ecologists and geomicrobiologists (Orphan, 2009). Below follow some examples of how FISH has been employed for some of the most widely explored ecosystems in geomicrobiology (see also images in Figure 2):

Aquatic systems: In general, successful FISH experiments can be performed on aquatic systems, since at least one of the main parameters for good microbial growth and dispersion of cells and nutrients, water, is abundant. Nevertheless, several parameters may introduce several biases, e.g., low nutrient status and/or naturally occurring

autofluorescing particles (Vesey et al., 1997). Aquatic systems with high nutrient content such as contaminated lakes or even anthropogenic systems like wastewater treatment plants will contain greater amounts of highly active bacteria than oligotrophic systems like aquifers and thus produce stronger FISH probe signals. For improved FISH on oligotrophic systems, different approaches have been undertaken:

Aquifers/ground water/drinking water: These ecosystems are generally dominated by planctonic cells in rather low cell numbers due to extreme conditions like oligotrophy, different redox states (e.g., anaerobic conditions), or toxic compounds (e.g., heavy metals, chlorinated drinking water or contaminated aquifers). Due to this, the general turn-over activities and thus also the ribosome content in the cells are generally extremely low. For adequate FISH evaluation, samples often need to be concentrated (e.g., by filtration) and confounding precipitates or debris removed (e.g., by cell extraction, Caracciolo et al., 2005). Early studies reported that standard FISH protocols may work well on certain aquatic samples like lakes and bottled water (Pernthaler et al., 1998; Glöckner et al., 2000; Watanabe et al., 2000; Flies et al., 2005; Loy et al., 2005); however, more recent studies report that either rainbow FISH (Sunamura and Maruyama, 2006) or CARD-FISH are more recommendable on drinking water or groundwater (Sekar et al., 2003; Nielsen et al., 2006; Wilhartitz et al., 2007; Meisinger et al., 2010a).

Ocean: Similar to the freshwater systems mentioned above, oceanic ecosystems are generally dominated by planctonic cells in rather low cell numbers. However, in contrast to the conditions in the aquifers in the subsurface, the cells in oceans are often exposed to more dynamic conditions. Despite this, the ribosome content in the cells and the turn-over activities may be rather low at least for certain species – depending on location and other conditions such as oxygen concentration, light frequencies, redox conditions, nutrient conditions, flux rates. For adequate FISH evaluation of cells, samples often need to be concentrated (e.g., by filtration) and confounding precipitates or debris must be removed (e.g., by cell extraction). Early studies demonstrated that standard FISH protocols may work well (Murray et al., 1998; Glöckner, 1999; Cottrell and Kirchman, 2000; Morris et al., 2004); however during the last decade, most studies have tried to increase probe signal intensities by modifying standard FISH protocols or applying other FISH tools like polynucleotide FISH (DeLong et al., 1999; Pernthaler et al., 2002; Preston et al., 2002) or CARD-FISH (Pernthaler et al., 2002a; b; Ishii et al., 2004; Teira et al., 2004; Herndl et al., 2005). In addition to this, various combinations with different activity targeted studies based on incubation with chloramphenicol (Ouverney and Fuhrman, 1997), radioactive substrates like thymidine (Pernthaler et al., 2002) or bromodeoxyuridine (BrdU, Pernthaler and Pernthaler, 2005), or other substrates such as amino acids

Fluorescence In Situ Hybridization (FISH), Figure 2 (Continued)

Fluorescence In Situ Hybridization (FISH), Figure 2 Demonstration of different images from different ecosystems produced by different FISH techniques.

(Ouverney and Fuhrman, 2000; Cottrell, 2000; Cottrell, 2003), have been undertaken.

Soil/sediments/subseafloor: Soil and sediments are rather difficult environments for successful FISH studies, as these habitats are extremely diverse, complex, and subject to harsh and fluctuating conditions in terms of, e.g., water content and redox conditions. Thus, more than most other ecosystems, the biosphere of microorganisms in soil is often characterized by micro-niches which may be exposed to dramatic changes with regard to space and time. In addition to this, many substances in soil or sediments produce strongly confounding background such as humic compounds, mineral precipitates or other microscopic particles of unknown character. For successful FISH experiments, two different main approaches have been made (for a review, see Schmid et al., 2006; Schmid et al., 2007): (1) Spatial separations of cells or micro-niches by approaches such as embedding and

sectioning of soil columns or by confocal laser scanning microscopy of soil aggregates, different cell extraction procedures such as density centrifugation or cation exchange membranes (McDonald, 1986; Smith and Stribley, 1994; Caracciolo et al., 2005; Kurola et al., 2005; Lunau et al., 2005; Bertaux et al., 2007), or flow cytometry (Kalyuzhnaya et al., 2006; Podar et al., 2007). (2) The second approach employed a variety of different FISH protocols. The early studies reported generally only partial success or even contradictory results between FISH and other analytical tools (Hahn et al., 1992; Ludwig et al., 1997; Zarda et al., 1997; Chatzinotas, 1998; Llobet-Brossa et al., 1998; Christensen, 1999; Hristova et al., 2000; Ravensschlag et al., 2000; Janvier et al., 2003; Kobabe et al., 2004; Rusch and Amend, 2004; Flies et al., 2005; Knittel et al., 2005). However, during the last years, most studies have now replaced the standard FISH tool with CARD-FISH and nanoSIMS (Ishii et al., 2004;

Mussmann et al., 2005; Schippers et al., 2005; Tal et al., 2005; Orphan 2009).

Karst regions/rock/deep biosphere: During the last decade, our understanding of the role of microorganisms and their interactions with rocks and minerals over geological timescales has expanded considerably. The interaction of minerals with water and microbes do not only influence soil fertility, transport compounds, and pollutants through the subsurface, but they also contribute to dissolution of rocks or precipitation of various mineral formations like speleothems in caves and may thus even play a key role in global climate change (Northup and Lavoie, 2001; Brown and Lee, 2007; Cockell and Herrera, 2008). Several attempts have been made to screen for microbial life in rocks and set up validated guidelines for this (Barton et al., 2001; Barton et al., 2006; Tobin et al., 1999). The reoccurring concern is to not only prove extant microbial processes (Orphan and House, 2009) but also current cellular-based in situ activities in often carbon-poor systems. Since it may be difficult to retrieve sufficient amounts of RNA or other activity biomarkers from these systems due to low cell counts and activities, FISH, in particular in combination with advanced tools like nanoSIMS, may play a crucial role for demonstrating whole cells with targetable genes (Orphan, 2009). Despite these obstacles, standard FISH as well as CARD-FISH protocols have been successfully applied on, e.g., microbial mats in association with water and energy-rich substances for life based on chemolithoautotrophy in rocky environments or caves (Engel et al., 2003; Macalady et al., 2006; Meisinger et al., 2007; Meisinger et al., 2010b). However, certain types of microbial mats may be strongly hampered by confounding background caused by various mineral precipitates (Engel et al., 2010; Koeberich, 2008). Rigid environments like calcified biofilms or speleothems thus demand sophisticated modifications of standard FISH protocols as well as CARD-FISH (e.g., Shiraishi et al., 2008).

Extremophiles in various geological environments: Extremophiles thrive in extreme ecosystems which are characterized by extreme physical or geochemical conditions. Such conditions may pose a particular challenge for FISH experiments. So far, FISH has only been practiced in certain types of extremophilic ecosystems with mixed success, e.g., in hot springs (Nubel et al., 2002; Simbahan et al., 2005; Nakagawa et al., 2006; Weidler et al., 2008), polar regions (Junge et al., 2004), halophilic systems (Rossello-Mora et al., 2003; Maturano et al., 2006), mines/bioleaching systems (Schrenk et al., 1998; Edwards et al., 1999; Bond et al., 2000; Takai, 2002; Baker et al., 2004), hydrothermal vents (Harmsen et al., 1997; Schrenk et al., 2003; Nakagawa et al., 2006), and methane hydrate seeps (Boetius and al, 2000).

Summary

FISH (fluorescence in situ hybridization) is a valuable tool for in situ identification of microbial community structure, cell morphology, dynamics and spatial distribution.

If combined with different analytical tools additional information of activity, function and interactions of different species on single cell level can be performed. However, for successful FISH experiments, it is crucial to optimize and validate all steps throughout the FISH protocol, ranging from proper sampling technique and fixation, selection of appropriate gene markers, hybridization conditions and relevant controls, to optimal detection and evaluation strategies.

Forams (for short)

Definition

Foraminifera (from ancient Greek “hole bearers”, refers to the pores that early observers recognized in the calcitic tests) are amoeboid, eukaryotic protists with a large network of very thin cytoplasm extrusions (reticulopodia). Most species produce a genetically fixed shell (test), made of organic matter, agglutinated particles, calcite, aragonite, high-magnesium calcite, or opaline silica. The tests may be either simple bowls or tubes, or branched, coiled, substructured, and ornamented in diverse complexity. Several thousand species are found living in modern oceans, and this number still increases. Several times more extinct species are recovered from the fossil record. Foraminifera are considered an order (sometimes a class) in paleontology, subdivided by the structure and composition of modern and fossil tests. They are ranked among the “Granuloreticulosa” in biology, characterized by (1) their branching and anastomosing networks of reticulopodia, (2) a rapid bidirectional transport of intracellular granules and membrane domains driven by specific tubulin assemblies, and (3) a complex alternation of sexual and asexual reproductive cycles. Genetic investigations led to the definition of the first rank group “Foraminifera” within the Supergroup “Rhizaria”. Independent from such rankings, they range among the most common, diverse, and ubiquitous groups of single celled, test building eukaryotes on earth.

Introduction

Numerous foraminiferal species indicate specific environmental conditions, and the first and last appearance of extinct species exactly indicates time intervals in earth history. Investigations on the chemical and isotopical composition of their calcitic tests reveal environmental drifts in global ice volumes, palaeo-temperatures and -salinities of marine water masses, and marine palaeo-productivity (Hemleben et al., 1989; Murray, 2006). Despite the long term and extensive attention on foraminifera in

taxonomy (Loeblich and Tappan, 1988) and environmental sciences (Sen Gupta, 1999), our comprehensions on their evolution and ecophysiology are still in transition. Molecular ecology and metagenomics applied to the study of microbial biodiversity are changing our view of the biosphere. An impressive extension of foraminiferal clades has been uncovered by such molecular tools: naked freshwater amoebians, naked marine giant amoebians, and giant deep-sea protists formerly considered of unknown origin, where added to the first rank group Foraminifera (Adl et al., 2005; Pawlowski and Burki, 2009). Even amoeboid parasites of terrestrial plants are supposed to reach out from this lineage (Archibald and Keeling, 2004). Efforts to couple the growing phylogenetic diversity of single-celled organisms with ecological function lead to the discovery of novel metabolisms, processes, and symbiosis, and thus to a reevaluation of the geobiochemical impact of pro- and eukaryotes (Moya et al., 2008).

Earth history

The earliest fossils presumed for the foraminiferal lineage reach back into the Mesoproterozoic, despite severe problems in defining even Ediacaran remainders (Dong et al., 2008). The Cambrian provides already several foraminiferal families with organic-walled or agglutinated tests (Benton, 1993). A significant eukaryote radiation occurs in the Ordovician, coincident with increasing nutrient supply, enhanced primary production, and the propagation of planktonic metazoan stages. Such amplified planktonic food chains sponsored increased flux rates of organic matter at the sea floor, and thus the radiation of planktotrophy (Nützel et al., 2006). The calcitic fusulinids start in the Silurian (Loeblich and Tappan, 1988), and extend into the first rhizarian, rock forming mass deposition of biogenic shallow water carbonates, from the Pennsylvanian to the Permian. The fusulinid clade develops all principal morphological adaptations known from modern benthic foraminifera sheltering phototrophic symbionts, thus these mass deposits should result from host–symbiont interactions (Anderson and Lee, 1991). The structure of modern marine primary production was based on the evolution of diatoms, coccoliths, and modern dinoflagellates in the Triassic to Jurassic (Falkowski et al., 2004). Restructuring and enhancing marine primary productivity to an elevated level is recorded by the boost of rotaliid foraminifera, modern metazoans, and increasing bioturbation (Martin et al., 2008). One tribe of calcitic foraminifera, the globigerinids, completely adapted to this new planktonic food chain, and started to enter a purely pelagic live style in the Middle Jurassic. The boost of rock forming biogenic carbonate (chalk) and silica (diatomite) production from these new planktonic systems, however, was delayed to the Cretaceous in the marine realm, and to the Eocene for lacustrine diatomites. The first major radiation of planktonic foraminifera occurred during the mid-Cretaceous. The density structure of the upper water

column and the formation of deeper water masses were altered by plate tectonic activities, a major long-term rise of global sea level, and an overall increase of global temperatures (Leckie, 1989; Martin et al., 2008). Following the massive mass extinction of planktonic foraminifera at the K/T boundary, symbiosis with phototrophic endosymbionts was one key factor for the radiation of Cenozoic lineages (Norris, 1996). The diversity of benthic foraminifera, and thus presumably their ecological demands and adaptations, were influenced more modestly. The first appearance of foraminiferal tests build up by opaline silica occurs in the Miocene, by the benthic foraminiferal suborder Silicoloculinina (Loeblich and Tappan, 1988). Enhanced terrestrial silica weathering and riverine silica input by grassland expansion offers a causally driven correlation, similar to marine diatom diversification (Falkowski et al., 2004).

Modern oceans

Planktonic foraminifera are most influential for the open marine calcite budget. Their annual flux rate of calcitic tests at 100 m water depth accounts for 1.3–3.2 Gt, equivalent to 23–56% of the global, open marine CaCO_3 flux. During most of the year, dissolution takes place within the upper water masses (>700 m water depth), and only 1–3% of the initially exported CaCO_3 reaches the seafloor. This biogeochemical pump is most influential for the alkalinity of surface and intermediate water masses. During short pulsed flux events, mass dumps of fast settling particles yield the major contribution to the formation of deep sea sediments. This pathway transfers 0.4–0.9 Gt CaCO_3 annually, accounting for 32–80% of the total deep-marine calcite budget (Schiebel, 2002). Maximum carbonate production appears in open ocean realms where symbiotic and non-symbiotic planktonic foraminifera occur syntopic (Zaric et al., 2006). The contribution of coccolithophores (mean 12%) and calcareous dinophytes (0–3.5%) is comparably small (Schiebel, 2002; Sarmiento et al., 2002). Planktic gastropods (pteropods) may add another 10% only locally (Schiebel, 2002). Phototrophic endosymbionts play a major role in the carbonate production of planktic foraminifera. Such endosymbionts are the key factor for the foraminiferal successes in nutrient depleted environments, and for their enhanced turnover (Hemleben et al., 1989; Lee, 2006).

One sixth of the global carbonate production is shared by reef complexes, dominated by symbiont-bearing corals, foraminifera, and coralline algae. With an annual production of 130 million tons of CaCO_3 , benthic foraminifera bearing phototrophic symbionts contribute nearly 5% of the annual present-day carbonate production in the world's reef and upper shelf areas (Langer, 2008). Marine benthic foraminifera without phototrophic symbionts are much more diverse, inhabiting all ocean realms from estuaries to deep ocean trenches. But their share in marine biogenic carbonate production ranges only near 1% (Langer, 2008). This is due to the rapidly decreasing

flux rate and nutritional value of organic matter reaching the deeper ocean floors (Altenbach and Struck, 2001). Deep-sea foraminifera have a metabolic turnover comparable to bacteria (Linke, 1992; Moodley et al., 2002), and their grazing rate exceeds that of common meiofaunal groups (Pascal et al., 2008). They have a considerable share in abyssal respiration rates (Witte et al., 2003), but this does not sum up to a significant impact in biogenic carbonate production.

Complete denitrification was observed as an endogenic metabolic pathway for benthic foraminifera in laboratory cultures (Risgaard-Petersen et al., 2006). The species facultatively switch to denitrification when high loads of organic matter are available in oxygen-depleted environments. Field observations in the upwelling region off Chile revealed that benthic denitrification is dominated by foraminifera, and not by bacteria (Høgslund et al., 2008). In view of the large benthic foraminiferal populations recovered from other oxygen minimum zones, and the large uncertainties in the global nitrogen budget (Gruber and Galloway, 2008), these findings may challenge our considerations on marine denitrification cycles (Høgslund et al., 2008). Several species related to denitrification acquire chloroplasts from settled algae in the deep ocean, which are kept functional in the foraminifers cytoplasm for at least one year (Grzymski et al., 2002). Such kleptoplasts produce hydroxyl radicals, which offer an alternative source of oxygen for the hosts metabolism by H_2O_2 breakdown (Bernhard and Bowser, 2008). Sulfur-oxidizing bacterial endosymbionts were considered for benthic foraminifera recovered from long-term sulfidic environments in the deep sea (Bernhard et al., 2006) and from temporal anoxic shelf areas (Bernhard, 2003). However, the definition of oxic or anoxic conditions is a problem by itself near the redox cline, as the interwoven, submillimetric structures of differing redox conditions build up a foamy, three dimensional space. Contrasting microbial turnover takes place in smallest pore water compartments. The interlacement may be so dense that foraminiferal inhabitants can not be attributed to either oxic or anoxic conditions (Bernhard et al., 2003).

Xenophyophores and Komokiaceans are very common deep-sea foraminifera with a comparatively large and loosely agglutinated test. They may cover up to 50% of hadal seafloors (Lemche et al., 1976). Early research on the role of Xenophyophores and Komokiaceans for biogenic metal dissolution and precipitation considered a significant impact for the formation of manganese nodules (Riemann, 1985). The microscopic barite crystals, commonly found in the endoplasm of Xenophyophores (Gooday and Nott, 1982), were considered a proof for their endogenic barite precipitation (Bertram and Cowen, 1997). However, these rhizarians ingest considerable amounts of highly refractory organic matter and produce large amounts of waste pellets (stercomata), offering an attractive food source for deep ocean microbial communities (Nozawa et al., 2006). Gardening of a specialized

bacterial flora growing on the stercomes of Xenophyophores was made plausible by Laureillard et al. (2004). Such affiliated microbial communities will move the redox state by degrading the stercomata, a factor that should interplay with the observed metal reactions.

Gathering refractory material that is transferred to higher levels of the food chain by bacterial counterparts is highly effective. Parallel to the increasing number of bacteria available as food, it can enhance the metabolic pathways of the host. Limited endogenous proteolytic capacities of benthic organisms are surpassed by enzyme sharing with bacteria, in most cases combined with the production of an agglutinated detrital lump or burrow (Riemann and Helmke, 2002). Benthic foraminifera from the earliest tribes to most recent lineages retain the ability to rapidly produce such detrital lumps or cysts, in addition to the genetically fixed test (Heinz et al., 2005). Most researchers make reasonable tropical adaptations and bacterial gardening for the common production of such cysts (Heinz et al., 2005).

Conclusions

The general outline of foraminiferal ecology and their overall impact on the marine food chains and calcite budgets is well documented and understood. Recently discovered, endogenic denitrification offers a facultative metabolic pathway for benthic foraminifera with potential impact for the marine nitrogen cycle. Additional complexity in synecology and ecophysiology is also indicated by observations on chemotrophic bacterial endosymbionts and bacterial gardening, not fully understood at present. Chemotrophic symbionts and functional kleptoplasts seem to play a key role for anoxic and sulfidic microenvironments. We may presume that foraminiferal interactions with bacteria play a more significant role in geobiology and biogeochemical cycles than has previously been suspected.

Frutexites, Figure 1 Original figures of genus of *Frutexites* described by Maslov (1960).

Definition

Frutexites is a problematic microfossil rich in iron. From a taxonomic point of view, only five species have been figured (*Frutexites arboriformis*, Maslov, 1960; *F. microstroma*, Walter and Awramik, 1979; *Frutexites* sp. 1, *Frutexites* sp. 2, and *New gen.* 3, Tsien, 1979), although the authors mostly use the term *Frutexites sensu lato*. The genus *Frutexites* was coined by Maslov (1960) in order to describe submillimeter-sized, iron-rich, and subordinate calcite microfossils (Figure 1). *Frutexites* have a dendritic shape formed by divergently branched microcolumns. The height and width of microcolumns as well as their composition and microstructure can vary (Table 1). The preservation of microstructure is strongly controlled by its dominant mono- or polymineral

character. Microstructure is formed by convex-upward laminae, which sometimes show radially arranged fibers.

Frutexites can occur mainly as monomineral as well as polymineral structures with: iron-rich and/or manganese-rich (hematites, iron hydroxides, Fe-Mn oxyhydroxides), and/or carbonate-rich (calcite, ferroan calcite, dolomite), and/or siliciclastic-rich (argillite, microquartz), and/or phosphatic-rich zones.

Depositional environmental occurrences

Frutexites has been described in marine environments such as shallow and deep water stromatolites, microbial limestones, hardgrounds, and condensed pelagic limestones as well as in cavities, sheet-cracks, veins, and Neptunian dikes. However, comparisons with

Frutexites, Table 1 Sizes, morphological and compositional parameters of *Frutexites* according to different authors

Authors	Height	Width	Microstructure	Morphology	Composition
Maslov (1960)	Up to 400 μm (see Figure 1)	25–30 μm , more of 50 μm	Sheets with occasionally circular spaces	Radially diverging and branched sheets	Iron hydroxide and carbonate
Horodyski (1975)	20–500 μm	10–200 μm	2–10 μm convex-upward laminae	Pillar-shaped branched and not	Hematite, calcite, and argillite
Walter and Awramik (1979)	Up to 450 μm	5–120 μm	0.7–2.7 μm convex upward laminae and axial tube (trichome?)	Undulose layers, laminae with protruding pustules and erect branching microcolumns	Organic matter permineralized by silica
Myrow and Coniglio (1991)	250 μm –4 mm, most <1 mm	75–600 μm , 250 μm average	Chambers, laminae, fibers, and projections	Unbranching and branching columns	Calcite, ferroan calcite, hematite, and microquartz
Böhm and Brachert (1993)	Up to 5 mm, average 1–2 mm		Convex laminae with radially arranged fibers		Fe-Mn oxides, calcite, and phosphates
Woods and Baud (2008)	Up to 800 μm	50–200 μm	Lighter and darker colored layers resulting chambered appearance		Hematite and/or Fe-Mn minerals, and calcite

Frutexites, Figure 2 (a) Marine Upper Cenomanian/Lower Turonian *Frutexites* colonies from a deepwater hardground environment (Lienres coast, northern Spain; Reitner et al., 1995). The *Frutexites* facies is located on top of the hardground sequence and marks a fundamental change of the oceanographic conditions. (b) Deep subterranean *Frutexites* colonies growing on calcareous microstromatolites from tectonic fractures in the so-called “sole dolomite” at the base of the Naukluft Nappe Complex (NNC) in southern Namibia. The colonies are growing upside down from the fracture ceiling. The black ones are rich in manganese oxides, the ochre parts are enriched in iron oxides.

Frutexites, Figure 3 (a) Net-like, mineralized microbial mat covering the surface of granitic rocks (Åspö Hard Rock Laboratory, Sweden). (b) Scheme of the Åspö-dropping microsystem, comprising a pending mineral cone as a fluid-conduit (1) and the evolving, net-like microstructure beneath, displaying a dark mineralized ridge (2) covering the laminated biofilm (3) and the central area directly exposed to the fluid dropping (4). (c) Close-up of the net-like, mineralized microbial mat, pointing to the dark mineralized ridge (2) and the bright central area (4) according to scheme b.

Frutexites, Figure 4 (a) Thick section of the mineralized, net-like, recent biofilm from the tunnel of Åspö (Sweden) under reflected light, revealing the typical laminated structure. These laminae predominantly consist of iron oxides and hydroxides. (b) UV-fluorescence microphotography exhibits *Frutexites*-like colonies within the laminae of the mineralized biofilm.

continental black shrubs are common, too. *Frutexites* structures are also frequently found in veins and fractures of deep subterranean environments (Figures 2b, 3, and 4).

Stromatolites

The main record of *Frutexites* has commonly been recognized from shallow to deep calcareous stromatolites from Proterozoic to recent examples (see Caldera lake stromatolites at Tonga, by Kazmierczak and Kempe, 2006). *Frutexites* structures grow upward perpendicular to the stromatolite laminae; however, they can sometimes cross them (Horodyski, 1975) and even destroy them. For this reason, Böhm and Brachert (1993) interpreted that stromatolite accretion was independent of *Frutexites*, which would act as dweller or secondary binder in the Jurassic deep water stromatolites from Germany and Austria. Descriptions about the associated macro- and micro-fauna in the *Frutexites*-bearing stromatolites are not

abundant. In the Canning Basin, the late Devonian *Frutexites*-bearing stromatolites show abundant meta-zoans in life position as crinoids and coral holdfasts encrusting the successive laminae (Playford et al., 1976), which would indicate normal oxygenated water conditions (Nicoll and Playford, 1993). In Jurassic stromatolites, *Frutexites* occur with shells of *Bositra* and *Lenticulina* foraminifers.

Cavities, sheet cracks, veins, and Neptunian dikes

The second most frequent occurrence of *Frutexites* in the geologic record is related to cavity walls and fissures. On the horizontal surfaces *Frutexites* could display a dominant upward growth, but, in general, their growth is normally perpendicular to the substrate where they were nucleated. *Frutexites* occur interbedded with fibrous calcite cements as well as with internal sediment. The oldest described record of *Frutexites* is in the Paleoproterozoic Gunflint chert (Walter and Awramik, 1979) and from sheet

cracks within stromatolites of the Upper Vendian to Lower Cambrian Chapel Island Formation, Canada (Myrow and Coniglio, 1991). *Frutexites* have been found in cavities of Devonian deep water mud mounds and grouped with *Renalcis-Epiphyton* calcimicrobes, and with deep water stromatolites assemblage (Tsien, 1979) as well as in stromatactoid cavities from Viséan microbial limestones where they occur interbedded with marine isopachous crusts of fibrous and botryoidal calcite cements (Gischler, 1996). The presence of *Frutexites* in Neptunian dikes has been described only in Devonian records from the Harz Mountains in Germany (Gischler, 1996) and mud mounds of the Hamar Laghdad Ridge in Morocco (Cavalazzi et al., 2007). Similar structures as *Frutexites* have also been described in voids from Toarcian Mn-rich layer at Tatra Mountains in Poland (Jach and Dudek, 2005) as well as in synsedimentary karstic cavities in Pleistocene travertines in Germany (Koban and Schweigert, 1993).

Condensed pelagic limestones and hardgrounds

The last most extended occurrence of *Frutexites* is associated with condensed hemipelagic and pelagic red to grey limestones like Griotte and Hallstatt Limestone as well as Rosso Ammonitico facies from Devonian up to Jurassic. These facies occur during very low sedimentation rates, from deep to relatively shallow water depths, during fast transgressive and/or drowning episodes. Nektonic organisms are the dominant fauna (goniatites, nautiloids, ammonoids) and *Frutexites* occur in (a) water-sediment interfaces colonizing sessile fauna, reworked bioclasts as well as ferromanganese hardgrounds (see below) and (b) within the micritic sediment. The first type of *Frutexites* growth in condensed pelagic limestones was described in Matagne Formation (Devonian of Belgium) by Tsien (1979) and in current-swept shallow pelagic ridge (Tafilalt Platform, Devonian of Morocco) by Wendt (1988). No less representative examples have been shown from the Triassic Hallstatt facies of Austria (Wendt, 1969; Rodríguez-Martínez et al., in press) and Oman Mountains (Woods and Baud, 2008). In the Oman Mountains, the sea-floor was directly colonized by *Frutexites*-bearing microbialites and synsedimentary cements. However, in the Northern Calcareous Alps, multiple ferromanganese crusts were colonized by epibenthonic sessile agglutinated foraminifers which were successively encrusted by *Frutexites* forming pillar-like structures above the seawater-sediment interface.

A similar situation has been described from deep-water hardgrounds during Mid-Cretaceous times in Spain (Reitner et al., 1995) (Figure 2). In this case, a previous benthic community dominated by coralline sponges was replaced by thick limonitic stromatolites with encrusting foraminifera and colonies of *Frutexites*.

The growth of *Frutexites* within the sediment was firstly pointed out by Böhm and Brachert (1993). They described the changes in composition and shapes of

Frutexites as a result of their growth in open spaces or in interstitial environments. Mamet and Pr  at (2006) found *Frutexites* associated to other hematite microstructures in condensed Griotte facies (Coumiac Limestones, Montagne Noire, Baleas Limestone Spain) and Rosso Ammonitico Limestone (Subbetic Cordillera Spain).

Continental environments

Some authors (Myrow and Coniglio, 1991; B  hm and Brachert, 1993) have compared the marine records of *Frutexites* with similar arborescent, dendritic forms found in speleothems, desert varnish, and travertines. Also, continental manganese and iron-rich black shrubs have been compared with the marine *Frutexites* records (Koban and Schweigert, 1993; Chafetz et al., 1998). Shapes, sizes, and polymineral character are similar in both marine and continental records.

Subterranean environments

Frutexites structures are sometimes common in light-independent, deep continental caves, fractures, and veins forming small microbial crusts often associated with calcareous stromatolitic structures. A characteristic representative was found by J. Reitner in southern Namibia (Figure 2b) at the base of the Naukluft Nappe Complex (NNC), which is part of the early Cambrian Damara orogeny (Miller, 2008). The deep base of the NNC is formed by the so-called "Sole Dolomite" (Korn and Martin, 1959) which is often heavily fractured. Within these cryptic fractures *Frutexites* is very common and intergrows with calcareous stromatolitic structures. Thin-shelled freshwater type ostracodes are also abundant in this fracture system.

A modern example of *Frutexites* structures has been found in the deep tunnel of   sp   in southern Sweden (Heim et al., 2007), as part of a highly oxygenated system. Wherever groundwater drops from the tunnel ceiling, a net-like, mineralized micro-system is formed on any rock surface beneath (Figure 3). In general, the dropping system is associated to pending mineral cones which are dominated by the iron-oxidizing, chemolithotrophic bacterium *Gallionella ferruginea*.

The evolving net-like structures feature semi-solid ridges, harboring a particular, highly diverse microbial community. The cross-section of this mineralized biofilm shows laminae with *Frutexites*-like structures (Figure 4). These are mainly composed of iron hydroxides, iron oxides, and less abundant manganese oxides. Small amounts of siderite, calcite, and siliceous material occur side by side with iron and manganese oxides.

Interpretation

Holotypes of *Frutexites* spp. (*Frutexites arboriformis*, Maslov, 1960; *Frutexites microstroma*, Walter and Awramik, 1979) were originally described from stromatolites; thus, they were genetically linked to different types of cyanobacteria (Playford et al., 1976, 1984; Scytonematacean – Walter and Awramik, 1979;

Rivulariacean – Hofmann and Grotzinger, 1985; Angulocellularia group – Riding, 1991). Hofmann and Grotzinger (1985) discussed the affinity of *Frutexites* to different cyanobacteria and proposed further alternatives (purely physicochemical accretion and/or iron bacteria due to the ferruginous character of stromatolite). The occurrence of *Frutexites* in cavities, fissures, and dykes was interpreted as a cryptobiont role (Myrow and Coniglio, 1991). However, Tsien (1979) was the first suggesting a non-phototrophic character, sometimes linked to chemoheterotrophic cyanobacteria (Gischler, 1996) or to chemohetero and autotrophic bacteria (Cavalazzi et al., 2007). Böhm and Brachert (1993) emphasized the roles of *Frutexites* as a cryptobiontic as well as a cryptoendopelitic organisms (living in interstitial habitats). Based on these aspects, the authors proposed the preference of *Frutexites* for oxygen-deficient environments (dysaerobic to anaerobic conditions). Furthermore, they suggested a bacterial precursor for the formation of *Frutexites* but did not exclude a possible fungal and/or physicochemical origin. According to previous publications (Maslov, 1960; Myrow and Coniglio, 1991), Böhm and Brachert (1993) explained the ferromanganese or phosphate mineralogy of *Frutexites* as a replacement of primary carbonate mineralogy. However, a primary iron mineralization of *Frutexites* was postulated by Horodyski (1975) and Hurley and Van der Voo (1990). Others like Hofmann and Grotzinger (1985) believed that microbiota involved in *Frutexites* could regulate the local water chemistry and iron oxyhydroxides as well as aragonite could coprecipitate.

Finally, the occurrence of *Frutexites* in condensed pelagic limestones and hardgrounds has been linked to a physicochemical origin (Wendt, 1969) as well as to iron bacteria (Reitner et al., 1995; Mamet and Pr  at, 2006). Reitner et al. (1995) interpreted the *Frutexites*–foraminifer assemblage as an R-strategic community which replaced the previous K-strategic community (sponges–microbes) due to fundamental changes in oceanographic conditions (from oligotrophic to more eutrophic conditions). Mamet and Pr  at discussed the origin of red pigmentation in some Phanerozoic limestones, where some condensed pelagic limestones with *Frutexites* are included. They argued that under anoxic to dysoxic conditions, ferrous iron may be available for oxidation by microaerophilic iron microbes growing at the sediment–water interface. In contrast, the recent *Frutexites*-like structures found in the deep biosphere in fact grow in air-exposed environments under aerobic conditions. However, the presence of different mineral phases within these structures could be associated to changing redox conditions and/or to a different microbial community composition at micrometer-range.

Conclusions

The different modes of growth of *Frutexites* have been recognized within shallow to deep water stromatolites,

on the seawater–sediment interface, marine micritic sediments, continental cavities, and fractures of deep subterranean environments. Such wider environmental distribution has been taken into consideration for paleoecological interpretations. According to the occurrence of *Frutexites*, some general aspects can be summarized: (a) its distribution does not show bathymetric control (although the dominant record is in deep waters facies), (b) it is formed in environments with very low sedimentation rate (in quiet as well as in agitated waters), (c) in marine environments, *Frutexites* mainly encrusts heterozoan assemblages (crinoids, sponges, solitary corals, and foraminifers), and finally, (d) there is no proof for an exclusive occurrence of *Frutexites* under anoxic and aphotic conditions.

Most of the authors considered a bacterially induced origin for *Frutexites*, but the final assessment strongly depends on which mineralogical composition they interpreted as primary (timing of iron mineralization) as well as its *loci* of growth.

FUNGI AND LICHENS

Bettina Weber, Burkhard B  del
 University of Kaiserslautern, Kaiserslautern, Germany

Definition

Fungi. Saprophytic, parasitic, or symbiotic living organisms, mainly filamentous (hyphae), rarely unicellular. Cell walls are of chitin or other non-cellulose compounds.
Lichens. Symbiotic organisms composed of a fungal partner, the mycobiont, and one or more photosynthetic partners, the photobiont.

Characteristics

Fungi

Fungi are a group of eukaryotic, heterotrophic organisms with their thallus on or in the substratum. The thallus can be unicellular (rarely) or filamentous (mostly), the latter being either composed of septate or nonseptate hyphae and often forming a more or less defined web of filaments (mycelium). The cell wall is typically chitinized or composed of other non-cellulose compounds. The spore forming thallus (sporocarp) can be microscopic or macroscopic with limited tissue differentiation. Fungi are cosmopolitan and ubiquitous, saprotrophic, mutualistic (mycorrhizal, lichen-forming), or parasitic. A number of rock-inhabiting fungi belong to the Deuteromycetes, a heterogenic group of fungi that develop no or only asexual sporocarp types. The vast majority of rock fungi are dark brown to blackish pigmented and are filamentous or forming microcolonies (B  del et al., 2000).

Lichens

Symbiotic mode of living

Lichens are mutualistic organisms consisting of a fungal partner, the mycobiont, and of one or more photosynthetic partners, the photobiont. Taxonomically speaking, they belong to the kingdom of fungi and represent here a special group, the lichenized fungi (Honegger, 1996). The lichen-forming fungi are polyphyletic, meaning that they have developed several times during the evolution of fungi. This brought about a taxonomically heterogeneous group with the large majority of them belonging to the Ascomycetes and only few Basidiomycetes and Deuteromycetes (= Fungi Imperfecti; Nash III, 1996a, Miadlikowska et al., 2006).

As photobiont of lichens, green algae with the most frequent genera *Trebouxia* and *Trentepohlia* make up about 90% of the photosynthetic partners, whereas cyanobacteria with the prevalent genus *Nostoc* account for the remaining 10%. The green algae, also referred to as “chlorobionts” (Lange and Wagenitz, 2003), belong to the eucaryotic algae which share many cytological features and their pigmentation (e.g., chlorophylls a and b) with land plants (Bold and Wynne, 1985; van den Hoek et al., 1993). Cyanobacteria (“cyanobionts”) are of

procaryotic nature, lacking a nucleus, mitochondria and chloroplasts, all of which are found in eucaryotic cells. The DNA, which in eucaryotic cells is stored within the nucleus, is found as circular DNA in the cytoplasm and also the thylacoids, which occur in the chloroplasts of eucaryotes, are here embedded into the cytoplasm (Friedl and Büdel, 2008).

The interactions between the mycobiont and photobiont are not completely balanced. There is metabolic transport from the autotrophic photobiont to the heterotrophic mycobiont in the form of carbohydrates, which passively leak from the photobiont cells. Metabolic transport processes from the mycobiont to the photobiont are not known (Schöller and Mollenhauer, 1997). However, the photobiont often also profits from growth within the mycelium of hyphae, since more balanced water and light conditions are granted within the thallus. Besides that, the mycobionts produce a variety of secondary substances that might be beneficial for the photobiont (Schöller and Mollenhauer, 1997). Therefore, the lichenization of the photobiont is probably most adequately described as a controlled parasitism by lichen-forming fungi (Ahmadjian, 1993).

The thallus of a lichen is formed by a more or less dense network of fungal hyphae, in which the photobionts are either evenly distributed (homoiomorous thalli), or are concentrated within a defined layer (heteromorous thalli). Homoiomorous thallus construction mainly occurs in gelatinous, crustose lichens (e.g., *Collema*, *Pyrenopsis*) whereas heteromorous thallus construction is typically formed by an upper cortex followed by a photobiont layer, a medulla and a lower cortex (Büdel and Scheidegger, 2008). A surface tissue, like the epidermis with stomata and a protective cuticle as in higher plants, does not exist in lichens, neither do they have water and nutrient-transporting structures.

Lichen morphology

The appearance of a lichen thallus is determined primarily by the mycobiont and only in few cases the photobiont determines, to a certain extent, the form of a thallus (e.g., in the filamentous genera *Coenogonium*, *Ephebe*, *Cystocoleus*, and *Rhacodium*). However, only after the establishment of the symbiosis, under the influence of the photobiont, the characteristic thallus of a lichen is developed (Büdel and Scheidegger, 2008).

Based on their overall growth form, lichens are traditionally divided into three main morphological types: crustose, foliose, and fruticose. Crustose lichens are tightly attached to the substrate with their lower surface and cannot be removed without destruction of the thallus. Foliose lichens form leaf-like thalli that are partly attached to the substrate and have a dorsiventral organization (Büdel and Scheidegger, 2008). Thallus lobes of fruticose lichens are hairlike, strap-shaped, flat, or cylindrical, forming erect or hanging thalli. Some fruticose genera like *Baeomyces* and *Cladonia* develop a twofold thallus with

a foliose horizontal and a fruticose vertical thallus part. Endolithic lichens represent a special form of crustose lichens, where the thallus partly or completely grows within the rock. According to Golubic et al. (1981), the endolithic growth form can be further separated into cryptoendolithic (= growing within the rock), chasmoendolithic (= growing along cracks or fissures of the rock), and euendolithic (= actively boring into the rock) organisms.

Diversity

Fungi

Rock-inhabiting fungi belong to major groups of fungi: the hyphomycetes and the “black fungi,” the latter named because of the strong production of melanoid pigments that causes dark-brown or blackish pigmented hyphae. Formation of microcolonies is a universal feature of the latter group, and they are therefore named “microcolonial fungi” (= MCF; Figure 1f and i; Gorbushina, 2003). Hyphomycetes form a mycelium but lack a sporocarp and the conidia (asexual spores) are borne on hyphae. They occur on soil or epiphytic habitats and dominate on rock surfaces under milder climate regimes (e.g., high air humidity, abundant nutrients). The black MCF prevail under harsh climatic conditions and are slow-growing. They represent a diverse assemblage of non-lichenized ascomycetes. Because of a convergent microcolonial morphology and their morphological plasticity, they are extremely difficult to identify by classical methods. Identification procedures based on molecular methods are just in progress and have been applied to a few strains only. So far, identified samples and strains have been placed in the mostly anamorphic (asexual) genera *Alternaria*, *Chaetomium*, *Cladosporium*, *Coniosporium*, *Cryomyces*, *Friedmanniomyces*, *Lichenothelia*, *Phaeococcomyces*, *Phaeosclera*, *Phoma*, *Sarcinomyces*, and *Scolecobasidium* (Sigler et al., 1981; Diakumaku et al., 1995; Wollenzien et al., 1997; Sterflinger et al., 1997; Büdel et al., 2000; Selbmann et al., 2005; Onofri et al., 2007). Most of them belong to the ascomycete order Pleosporales, Capnodiales, and Dothideales, summarized in the class Dothideomycetes (Schoch et al., 2006), few belong to the Chaetothyriales in the class Eurotiomycetes (Geiser et al., 2006).

Lichens

Lichens grow on a wide variety of substrates including rocks (= epi- or endolithic), soil (= epigeic), detritus, and the branches, stems (= epiphytic), and leaves of trees (= epiphyllic). Most lichen species are specialized to one type of substrate comprising certain habitat characteristics. There are species with a wide ecological amplitude (euryoecious as compared to stenoecious species), able to colonize different types of substrate, like e.g., *Caloplaca citrina* (Hoffm.) Th.Fr., *Candelariella vitellina* (Hoffm.) Müll.Arg., and *Physcia adscendens* (Fr.) Oliv.,

Fungi and Lichens, Figure 1 (a) Granite inselberg at Soebatsfontein, Succulent Karoo, South Africa. (b) Close-up of the rock surface, showing dense colonization by the microlichens *Peltula bolanderi* (large olive-colored thalli), *Peccania* sp., *Synalissa* sp., cyanobacteria, and microcolonial fungi. (c) Detail with *Peccania* sp. (d) Detail with *Synalissa* sp. (e) Microscopical view on the lobes of *Synalissa* sp., showing the incorporation of the yellow pigment scytonemin (light and UV protectant) in the gelatinous sheath of the lichen. (f) Endolithic lecidoid lichen, thallus parts visible; where the rock surface was removed (arrows), the sporocarps (fruit bodies) are exposed on the rock surface (fb); MCF indicates the presence of numerous microcolonial fungi. (g) Microscopical view on a part of the algal layer of the endolithic lecidoid lichen showing the *Trebouxia*-like chlorobionts in an envelope of lichen hyphae. (h) Colonies of the red-sheathed cyanobacterium *Gloeocapsa* sp. growing on the rock surface between the lichens. (i) Microcolonial fungi on the rock surface.

and there are nutrient-tolerant species that occur epiphytically as well as epilithically (Figure 2b and c; Wirth, 1995).

On soils, lichens often represent part of a biological soil crust (BSC). BSC are formed by an association between soil particles and different proportions of cyanobacteria, algae, microfungi, bryophytes, and lichens (Belnap et al., 2003). In arid and semiarid regions, which make up more than 30% of the land surface of the earth, BSC cover up to 25% of the soil surface (Weber et al., 2008), but also in temperate regions like Central Europe, BSC occur in various habitats (Büdel, 2003).

Rock-inhabiting lichens come from most taxonomic groups of lichens as, for example, members of the class Lichinomycetes (e.g., *Anema*, *Digitothyrea*, *Heppia*, *Lichinella*, *Peccania*, *Peltula*, *Phyllisciella*, *Synalissa*, *Thyrea*; Figure 1b–e) that exclusively have cyanobacteria as photobionts. Although these lichens can be most abundant in arid and semiarid landscapes, the vast majority of lichens (more than 200 species) come from the largest class of lichenized fungi, the Lecanoromycetes. Within the Lecanoromycetes, green algal photobionts dominate (e.g., *Acarospora*, *Buellia*, *Caloplaca*, *Dermatiscum*, *Dimelaena*, *Hymenelia*,

Fungi and Lichens, Figure 2 (a) Vegetation pattern of lichens on a natural rock surface (dolomite, Untersberg, Austria). *Hymenelia coerulea* (grayish blue areas), *Hymenelia prevostii* (white, arrows), both endolithic growing lichens. (b) Lichen community colonizing mortar of medieval churches (built in the thirteenth to fifteenth centuries, Mecklenburg-Western Pomerania, Germany) consisting of *Caloplaca citrina* (Hoffm.) Th.Fr., *Caloplaca saxicola* (Hoffm.) Nordin, and *Lecanora dispersa* (Pers.) Sommerf. (c) Damp lower part of north-exposed wall of rural church built on a field stone foundation and brick walls joined with mortar. Lichen community consisting of *Enterographa zonata* (Körb.) Torrente & Egea, *Haematomma ochroleucum* (Neck.) J.R.Laundon, *Ramalina pollinaria* (Westr.) Ach., *Xanthoria calcicola* Oxner and *Lepraria incana* (L.) Ach. (Mecklenburg-Western Pomerania, Germany). (d) Endolithic growing lichen *Caloplaca* sp., growing on sandstone of the Clarens formation, Golden Gate Highlands National Park, South Africa. This lichen is actively weathering the rock; note the rim of the rock at the margin of the lichen, indicating the original rock surface.

Lecidea, *Lecanora*, *Lepraria*, *Rinodina*, *Parmelia*, *Parmotrema*, *Usnea*, *Verrucaria*, *Xanthoparmelia*; Figure 2a).

Apart from natural habitats, lichens also grow on artificial substrates like mortar and building stone (Figure 2b and c; e.g., Ariño and Saiz-Jimenez, 1996; Weber and Büdel, 2001), wooden material like fences and benches, and even glass, bone, tyres, and metal under favorable climatic conditions (Schöller, 1997).

Biogeography

Fungi

Since determination on the species level is a challenging task and not easily possible without culturing or before more molecular data are available, biogeographical information is very limited at present. For some species of the genus *Lichenothelia*, however, information on distribution patterns are available. While *L. intermedia* occurs on almost every granite rock surface throughout Africa, the species *L. gigantea* and *L. radiata* are restricted to Australia, and *L. globulifera* was only found on rock outcrops of the Seychelle island La Digue (Henssen 1987). On the basis of morphological and molecular data (SSU phylogeny and ITS sequence data), Selbmann et al. (2005) recently described two new genera of MCF, *Cryomyces*, and *Friedmanniomyces*, only known from Antarctic rocks so far. The authors provide good evidence that at least the new genus *Cryomyces* might be endemic to Antarctica. Since MCF diaspores are easily spread over large distances by the wind, many of them might have a cosmopolitan distribution (airborne fungi).

Lichens

Lichens have developed during evolutionary radiation of ascomycete fungi within the last 600–400 million years, possibly contemporaneous to the emergence of land plants (Galloway, 1996). Due to this long-lasting evolutionary process, their distribution patterns show similarities to other groups of organisms and can be explained utilizing the theory of plate tectonics (Galloway, 1996). Compared to vascular plants, lichens comprise a higher number of cosmopolitan species within different climate zones of the earth and endemism within smaller geographic regions is normally lower. Exemplarily, on the Kap Verde Islands 13.4% of vascular plants were endemics, whereas only 2.5% of the lichen species were found to be endemic (Schöller, 1997). Dispersal of both symbiotic partners is facilitated by the fact that fungal spores as well as algal cells are transported over vast distances within the air (Brown et al., 1964).

At least 16 major distribution patterns of lichens can be distinguished (Galloway, 1996). Besides lichen species that are constrained to one single continent, like austral and neotropical taxa, there are distribution patterns that comprise spatially contiguous regions, like the paleotropics that include most of Africa, the Arabian Peninsula, most of the Indian subcontinent, the Malaysian archipelago, and the Islands of the Pacific Ocean (Galloway, 1996). A third type of distribution pattern embraces disjunct distributions over continents, which have been close by or unified in history, but were separated by plate tectonic movements, like pantropical and American–Asian distribution patterns (Grotzinger et al., 2006). Taxa with bipolar distribution represent the last pattern, which results from climate change through earth history. These organisms occur at high latitudes of the

northern and southern hemisphere, but often also occur in alpine regions, forming relict habitats of the last ice age (Galloway, 1996).

Physiology

Fungi

There is not much known of the specific physiology of rock-inhabiting fungi except that they are able to tolerate extremely high (70–80°C; Palmer et al., 1987) and low temperatures (–40°C; Selbmann et al., 2005) due to their poikilohydric nature and related to that, their ability to withstand long periods (in the magnitude of tens of years) in the dry state. Many fungi are heavily melanized, most probably as a shelter against high radiation of both visible and UV light.

Lichens

Lichens are poikilohydric organisms, meaning that they cannot actively take up or lose water. Moistening of the thallus can be achieved by rain/snow precipitation, dew-fall, and equilibrium with high air humidity. This clearly distinguishes them from vascular plants that actively regulate water uptake and loss.

Water

Although water uptake, storage, and loss are modified by differences in thallus structure and morphology, these mechanisms are predominantly controlled by physical processes (Rundel, 1988). Therefore, the physiological activity of lichens is highly dependent on the prevailing water conditions. In general, the photosynthetic response of lichens to increasing water content can be described as an optimum curve, which, however, reveals large variability (Lange et al., 2001). Air-dried lichens with a water content below 15–30% show no photosynthetic response at all (Nash III, 1996b). With increasing water content, lichens first reveal net respiration rates before the compensation point is reached, above which positive photosynthetic activity is recorded. In general, cyanolichens commence positive net photosynthesis (NP) at higher water contents and are generally able to perform positive NP under higher water content than chlorolichens (especially the homoimerous species; Lange et al., 2001).

Above an optimum water content, at which maximum NP rates are reached, free water is present and the lichens have a water potential close to zero (Green and Snelgar, 1982). These periods of water supra-saturation cause a depression in photosynthesis by increased thallus diffusive resistances; CO₂ pathways within the thallus are blocked by water (Lange et al., 1997). Water supra-saturation can occur in chloro- and cyanolichens of all growth forms (Lange et al., 1996, 2000, 2004; Lange and Green, 1997), and also endolithic lichens of various substrates have to cope with this problem (Tretiach and Pecchiari, 1995; Tretiach and Geletti, 1997; Winkler and Kappen, 1997). In a recent study, the photosynthetic

performance of *Hymenelia prevostii* and *H. coerulea*, two endolithic green algal lichens growing on steep limestone outcrops in the eastern alpine mountains, have been investigated in detail (Weber et al., 2007). Both species were saturated at extremely low water content (*H. prevostii*: 0.26 mm, *H. coerulea*: 0.07 mm rainfall equivalent) and revealed very narrow ranges of positive NP values upon increasing thallus water content (0.2 mm vs. 0.1 mm). Their growth on steep rock surfaces therefore represents an adaptation to avoid excessively high water contents or the formation of CO₂ blocking water films.

A crucial difference in the physiology of cyano- and chlorolichens lies in the capability to use water vapor for photosynthetic activation. While air-dry chlorolichens gain positive NP in equilibrium with air of about 80% relative humidity and above, all cyanobacterial lichens investigated so far need liquid water for activation of NP (Büdel and Lange, 1991; Lange et al., 1993). This fundamental difference also affects the natural habitats of lichens with cyanolichens preferably occurring at moist habitats with frequent liquid water (e.g., *Collema* spp., *Lichinella* spp.), whereas green algal lichens often also occur in rain-shaded habitats of high air humidity (e.g., *Lepraria* spp., *Usnea* spp.). The endolithic *Hymenelia* species mentioned above were also shown to perform positive NP at relative air humidities of 90% and above (Weber et al., 2007).

Light

The capture of radiant energy is essential for photosynthesis. Only light of wavelengths between 400 and 780 nm, the photosynthetically active radiation (PAR), is utilized for photosynthesis (Nash III, 1996b). Under constant and favorable abiotic conditions, photosynthetic response of lichens to increasing light intensities exhibits a saturation curve with saturation for most species occurring between 100 and 400 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Demmig-Adams et al., 1990). However, extremely shade-tolerant species have saturation values as low as 20 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Green et al., 1991), whereas others, like *Ramalina maciformis* (Del.) Bory reveal values above 1,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Demmig-Adams et al., 1990). At increasing temperatures, light saturation is achieved at higher levels (Kershaw, 1985) and also water content has an influence (Lange, 1969), probably due to alterations of light penetration within the thallus (Ertl, 1951; Dietz et al., 2000). Exposure of fully hydrated lichens to excess light can induce a depression of photosynthesis, both in chloro- and cyanolichens (Demmig-Adams et al., 1990).

As a protection against excessive light, lichens in general possess a cortex made of fungal tissue, and some species even form a so-called epinecral layer consisting of dead, collapsed, and often gelatinized hyphae and photobiont cells (Büdel and Scheidegger, 2008). *Peltigera rufescens* (Weiss) Humb., for example, has a cortical organization that causes a decrease of light transmittance to

40% at the upper boundary of the algal layer (Dietz et al., 2000).

The endolithic growth form (Figure 1f) can also be interpreted as a protection from excess light. Winkler and Kappen (1997) found that only 0.1–0.2% of the ambient light reaches the upper part of the algal layer in *Sarcogyne* cf. *austroafricana* (Zahlbr.) H. Magn. Light reduction within the sandstone on top of the photosynthetically active layer is also reflected by light saturation values above 800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ measured for *Sarcogyne* cf. *austroafricana*, *Lecidea* aff. *sarcogynoides* Körb., *Lecidea confluenta* Müll. Arg. and *Lithoglypha aggregata* Brusse (Winkler and Kappen, 1997). In limestone, *Hymenelia prevostii* and *H. coerulea* were saturated at high light intensities (1,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ vs. 800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$; Weber et al., 2007).

Temperature

Lichens are generally known to survive a wide range of temperatures. Being dominant terrestrial organisms of Antarctica, they must be able to tolerate extremely low temperatures (Nash III, 1996b), whereas in sun-exposed microhabitats, lichens experience temperatures of up to 60°C (Hahn et al., 1989). However, lichens in general reveal a vast difference in temperature tolerance depending on whether the thalli are hydrated or dry. Whereas dry thalli of some lichen species are able to tolerate a stepwise cooling to temperatures as low as –196°C (Kappen, 1973) and heating up to 90 or 100°C (Lange, 1953), wet thalli are by far more sensitive. Review of field measurements of lichen photosynthesis revealed that many lichens are primarily active at temperatures between 5°C and 20°C, although 0–10°C may better characterize some Antarctic species (Kappen, 1988; Kappen and Friedmann, 1983).

Photosynthetic capacity of some lichen species is known to reveal seasonal changes that involve an adjustment to higher summer temperatures (Kershaw, 1985). Recently, Lange and Green (2005) proved that dark respiration (DR) of lichens does exhibit seasonal changes of temperature sensitivity. At 5°C, for example, the respiration rates of *Cladonia convoluta* (Lam.) P.Cout., *Lecanora muralis* (Schreber) Rabenh., and *Diploschistes muscorum* (Scop.) R.Sant. were several times higher in winter than in summer. This acclimation of DR implies that maximal net carbon fixation rates remain similar throughout the year and are not depressed by increased carbon loss due to higher temperatures during the warmer season (Lange and Green, 2005).

CO₂

The photosynthetic CO₂-fixation rate of lichens at optimal water content generally increases with increasing CO₂-concentrations, typically reaching saturation around 600–1,300 ppm (Nash III, 1996b; Tretiach and Geletti, 1997; Lange et al., 1999; Lange, 2002). At natural CO₂ concentrations (around 360 ppm), many species only

reach about 60–80% of maximal NP under optimal water conditions (Lange et al., 1999; Lange, 2002).

Under supra-saturated water conditions, NP of lichens is often depressed at natural CO₂ concentrations. Increased CO₂ values, however, in most cases result in attenuation of this depression (e.g., Lange, 2002). In some species, as for the epigeic species *Fulgensia fulgens* (Sw.) Elekin, a severe depression in CO₂ uptake can even be completely counterbalanced by a CO₂ concentration of 4,500 ppm (Lange et al., 1999).

The CO₂ compensation point (CO₂ concentration, at which respiration equals photosynthesis) in many lichen species is very low as compared to vascular plants (Nash III, 1996b). This often results from a CO₂ concentrating mechanism (CCM), by which CO₂ is actively pumped into the photobiont cells (Badger et al., 1993). Such a CCM is also present within the photobiont *Trebouxia irregularis* Hildreth and Ahmadjian of the endolithically growing *Hymenelia* species, which makes them less susceptible to elevated CO₂ concentrations (Weber et al., 2007).

Interactions with the substrate

Bare natural rock surfaces are extremely rare on earth and might only be found under extreme climatic conditions of hot or cold deserts. Normally, rock surfaces are covered by a dense layer (film, crust; Figure 1a) composed of cyanobacteria (Figure 1h), algae, lichens (Figure 1b–f), and fungi (Figure 1f and i). Cyanobacteria, lichens, and fungi also can grow inside the rock itself, in the upper few millimetres (= endolithic, Figure 1f and g). On inselbergs of tropical savannas, these biofilms are even responsible for the characteristic black (cyanobacteria dominated) or brown color (lichen dominated) of the rock surface (Büdel et al., 2000).

Fungi

Fungi grow on rock surfaces (epilithic), inside the rock (endolithic) or are part of the desert varnish produced by microorganisms growing inside the up to 1 cm thick black layer (e.g., Krumbein and Jens, 1981). Also MCF have been shown to be involved in desert varnish formation in Arizona and Australia (Taylor-George et al., 1983). Microbial growth on rock surfaces follows the microscopic landscape formed by mineral grains, pores, and fissures of the substratum (Figure 1f and i). Characteristically, microorganisms of the resulting biofilms colonize in the way that fungal hyphae and some cyanobacteria penetrate the substrate, while algae, bacteria, and microcolonies of yeast-like fungi clump together (Gorbushina, 2007). They secrete extracellular polymeric substances (EPS), which envelope the microcolonies, keep them together and adhere them to the substratum.

Biogenic rock weathering is surely a multifactorial process. The role of fungi in the wear-down of rocks is difficult to separate from the activity of other microorganisms of biofilms. Generally, there are two main groups of weathering that can be distinguished. (1) Either the growth of cells forces separation of mineral grains (Dornieden

et al., 1997), or desiccation/hydration cycles of cell walls and EPS cause their separation (Friedmann and Weed, 1987; Warscheid et al., 1991). (2) Dissolution of rock minerals can be achieved by organic acids released from cells, chemical impact of respiratory CO₂, H⁺, and redox reactions with metal-ions (Gadd, 1999; Burford et al., 2003).

Lichens

During the 1980s and 1990s, a huge variety of literature on the patterns and effects of biogenic weathering by lichens has been published. However, a comprehensive understanding on the overall mechanisms, effects, and magnitude of effects could not yet be accomplished (Chen et al., 2000).

As for the fungi, the impact of lichens can be subdivided into physical and chemical effects. The physical effects comprise: (1) penetration of hyphae through intergranular cavities and along mineral cleavage planes; (2) thallus expansion and contraction due to varying water content; (3) freezing and thawing of the lichen thallus; (4) swelling of organic and inorganic salts originating from lichen activity; and (5) incorporation of mineral fragments into the thallus (Chen et al., 2000).

The chemical effects comprise the solubilization and the insolubilization of inorganic elements, resulting in the weathering of minerals (silicates, phosphates, carbonates, sulfides, oxides) and the formation of new deposits (carbonates, oxides, sulfides, phosphates; Benthelin, 1988). The solubilization processes, as induced by lichens include (1) the release of metal ions by acid and complexing compounds, and (2) the acidification or alkalization by uptake or release of alkaline compounds. Insolubilization processes are oxidation of Fe²⁺ and Mn²⁺, and uptake of elements by the organisms in different environments (Benthelin, 1988).

Besides the alkalization activity of endolithic cyanobacteria (Büdel et al., 2004), it is also expected that lichens perform a similar role on/in rocks. Wessels and Schoeman (1988) describe an exfoliation process initiated by the endolithic lichen *Lecidea* aff. *sarcogynoides* Koerb. In SEM imagery, they perceived a dissolution of the binding material along the growth zone of the hyphae and also pitting marks on the quartz crystals were observed, where hyphae had attached to the surface of the crystals (Wessels and Schoeman, 1988). Besides *L. aff. sarcogynoides*, also lichens of the genus *Caloplaca* are found to contribute to rock weathering in sandstones of South Africa (Figure 2d). Friedmann (1982) and Friedmann and Weed (1987) report on cryptoendolithic microorganisms in the Antarctic cold desert (Ross Desert) being dominated by lichens that cause a exfoliative weathering pattern along the lichen growth zone very similar to the pattern described by Büdel et al. (2004).

Conclusions

Identification of lichens on the basis of their external and internal morphology, as well as chemical characteristics, is well-established and only in some cases, where lichens

do not express a typical morphology or where they are often sterile, e.g., in the endolithic habitat, additional identification methods, using a molecular approach are necessary. Thus, lichen diversity of different rock types is quite well-known. Rock-inhabiting fungi, on the other hand, are much more difficult to identify. They often only express a reduced set of morphological features, insufficient for save identifications. Here, the use of molecular techniques is a must and already lead to a considerable increase in knowledge (e.g., Selbmann et al., 2005).

The interaction of fungi and lichens with their rock substratum is manifold. Biofilms with fungi and lichens might either increase weathering rates of their substratum, or in some cases, protect it from weathering. However, these crusts and films on rocks are a complex mixture of bacteria, cyanobacteria, algae, fungi, and microlichens embedded in the common structure of an EPS. Macrolichens rising above the biofilm form a separate layer, comparable to that of emergent trees that rise above the canopy of rain forests.

Microbial biodiversity of rock surfaces and the complex interaction of these organisms among themselves and with the rock substratum, for example, their role in bioweathering, is still poorly understood at present and will surely be a field of intensive and fascinating research in future.

Frutexites, Figure 1 Original figures of genus of *Frutexites* described by Maslov (1960).

Definition

Frutexites is a problematic microfossil rich in iron. From a taxonomic point of view, only five species have been figured (*Frutexites arboriformis*, Maslov, 1960; *F. microstroma*, Walter and Awramik, 1979; *Frutexites* sp. 1, *Frutexites* sp. 2, and *New gen.* 3, Tsien, 1979), although the authors mostly use the term *Frutexites sensu lato*. The genus *Frutexites* was coined by Maslov (1960) in order to describe submillimeter-sized, iron-rich, and subordinate calcite microfossils (Figure 1). *Frutexites* have a dendritic shape formed by divergently branched microcolumns. The height and width of microcolumns as well as their composition and microstructure can vary (Table 1). The preservation of microstructure is strongly controlled by its dominant mono- or polymineral

character. Microstructure is formed by convex-upward laminae, which sometimes show radially arranged fibers.

Frutexites can occur mainly as monomineral as well as polymineral structures with: iron-rich and/or manganese-rich (hematites, iron hydroxides, Fe-Mn oxyhydroxides), and/or carbonate-rich (calcite, ferroan calcite, dolomite), and/or siliciclastic-rich (argillite, microquartz), and/or phosphatic-rich zones.

Depositional environmental occurrences

Frutexites has been described in marine environments such as shallow and deep water stromatolites, microbial limestones, hardgrounds, and condensed pelagic limestones as well as in cavities, sheet-cracks, veins, and Neptunian dikes. However, comparisons with

Frutexites, Table 1 Sizes, morphological and compositional parameters of *Frutexites* according to different authors

Authors	Height	Width	Microstructure	Morphology	Composition
Maslov (1960)	Up to 400 μm (see Figure 1)	25–30 μm , more of 50 μm	Sheets with occasionally circular spaces	Radially diverging and branched sheets	Iron hydroxide and carbonate
Horodyski (1975)	20–500 μm	10–200 μm	2–10 μm convex-upward laminae	Pillar-shaped branched and not	Hematite, calcite, and argillite
Walter and Awramik (1979)	Up to 450 μm	5–120 μm	0.7–2.7 μm convex upward laminae and axial tube (trichome?)	Undulose layers, laminae with protruding pustules and erect branching microcolumns	Organic matter permineralized by silica
Myrow and Coniglio (1991)	250 μm –4 mm, most <1 mm	75–600 μm , 250 μm average	Chambers, laminae, fibers, and projections	Unbranching and branching columns	Calcite, ferroan calcite, hematite, and microquartz
Böhm and Brachert (1993)	Up to 5 mm, average 1–2 mm		Convex laminae with radially arranged fibers		Fe-Mn oxides, calcite, and phosphates
Woods and Baud (2008)	Up to 800 μm	50–200 μm	Lighter and darker colored layers resulting chambered appearance		Hematite and/or Fe-Mn minerals, and calcite

Frutexites, Figure 2 (a) Marine Upper Cenomanian/Lower Turonian *Frutexites* colonies from a deepwater hardground environment (Liencrees coast, northern Spain; Reitner et al., 1995). The *Frutexites* facies is located on top of the hardground sequence and marks a fundamental change of the oceanographic conditions. (b) Deep subterranean *Frutexites* colonies growing on calcareous microstromatolites from tectonic fractures in the so-called “sole dolomite” at the base of the Naukluft Nappe Complex (NNC) in southern Namibia. The colonies are growing upside down from the fracture ceiling. The black ones are rich in manganese oxides, the ochre parts are enriched in iron oxides.

Frutexites, Figure 3 (a) Net-like, mineralized microbial mat covering the surface of granitic rocks (Åspö Hard Rock Laboratory, Sweden). (b) Scheme of the Åspö-dropping microsystem, comprising a pending mineral cone as a fluid-conduit (1) and the evolving, net-like microstructure beneath, displaying a dark mineralized ridge (2) covering the laminated biofilm (3) and the central area directly exposed to the fluid dropping (4). (c) Close-up of the net-like, mineralized microbial mat, pointing to the dark mineralized ridge (2) and the bright central area (4) according to scheme b.

Frutexites, Figure 4 (a) Thick section of the mineralized, net-like, recent biofilm from the tunnel of Åspö (Sweden) under reflected light, revealing the typical laminated structure. These laminae predominantly consist of iron oxides and hydroxides. (b) UV-fluorescence microphotography exhibits *Frutexites*-like colonies within the laminae of the mineralized biofilm.

continental black shrubs are common, too. *Frutexites* structures are also frequently found in veins and fractures of deep subterranean environments (Figures 2b, 3, and 4).

Stromatolites

The main record of *Frutexites* has commonly been recognized from shallow to deep calcareous stromatolites from Proterozoic to recent examples (see Caldera lake stromatolites at Tonga, by Kazmierczak and Kempe, 2006). *Frutexites* structures grow upward perpendicular to the stromatolite laminae; however, they can sometimes cross them (Horodyski, 1975) and even destroy them. For this reason, Böhm and Brachert (1993) interpreted that stromatolite accretion was independent of *Frutexites*, which would act as dweller or secondary binder in the Jurassic deep water stromatolites from Germany and Austria. Descriptions about the associated macro- and micro-fauna in the *Frutexites*-bearing stromatolites are not

abundant. In the Canning Basin, the late Devonian *Frutexites*-bearing stromatolites show abundant meta-zoans in life position as crinoids and coral holdfasts encrusting the successive laminae (Playford et al., 1976), which would indicate normal oxygenated water conditions (Nicoll and Playford, 1993). In Jurassic stromatolites, *Frutexites* occur with shells of *Bositra* and *Lenticulina* foraminifers.

Cavities, sheet cracks, veins, and Neptunian dikes

The second most frequent occurrence of *Frutexites* in the geologic record is related to cavity walls and fissures. On the horizontal surfaces *Frutexites* could display a dominant upward growth, but, in general, their growth is normally perpendicular to the substrate where they were nucleated. *Frutexites* occur interbedded with fibrous calcite cements as well as with internal sediment. The oldest described record of *Frutexites* is in the Paleoproterozoic Gunflint chert (Walter and Awramik, 1979) and from sheet

cracks within stromatolites of the Upper Vendian to Lower Cambrian Chapel Island Formation, Canada (Myrow and Coniglio, 1991). *Frutexites* have been found in cavities of Devonian deep water mud mounds and grouped with *Renalcis-Epiphyton* calcimicrobes, and with deep water stromatolites assemblage (Tsien, 1979) as well as in stromatactoid cavities from Viséan microbial limestones where they occur interbedded with marine isopachous crusts of fibrous and botryoidal calcite cements (Gischler, 1996). The presence of *Frutexites* in Neptunian dikes has been described only in Devonian records from the Harz Mountains in Germany (Gischler, 1996) and mud mounds of the Hamar Laghdad Ridge in Morocco (Cavalazzi et al., 2007). Similar structures as *Frutexites* have also been described in voids from Toarcian Mn-rich layer at Tatra Mountains in Poland (Jach and Dudek, 2005) as well as in synsedimentary karstic cavities in Pleistocene travertines in Germany (Koban and Schweigert, 1993).

Condensed pelagic limestones and hardgrounds

The last most extended occurrence of *Frutexites* is associated with condensed hemipelagic and pelagic red to grey limestones like Griotte and Hallstatt Limestone as well as Rosso Ammonitico facies from Devonian up to Jurassic. These facies occur during very low sedimentation rates, from deep to relatively shallow water depths, during fast transgressive and/or drowning episodes. Nektonic organisms are the dominant fauna (goniatites, nautiloids, ammonoids) and *Frutexites* occur in (a) water-sediment interfaces colonizing sessile fauna, reworked bioclasts as well as ferromanganese hardgrounds (see below) and (b) within the micritic sediment. The first type of *Frutexites* growth in condensed pelagic limestones was described in Matagne Formation (Devonian of Belgium) by Tsien (1979) and in current-swept shallow pelagic ridge (Tafilalt Platform, Devonian of Morocco) by Wendt (1988). No less representative examples have been shown from the Triassic Hallstatt facies of Austria (Wendt, 1969; Rodríguez-Martínez et al., in press) and Oman Mountains (Woods and Baud, 2008). In the Oman Mountains, the sea-floor was directly colonized by *Frutexites*-bearing microbialites and synsedimentary cements. However, in the Northern Calcareous Alps, multiple ferromanganese crusts were colonized by epibenthonic sessile agglutinated foraminifers which were successively encrusted by *Frutexites* forming pillar-like structures above the seawater-sediment interface.

A similar situation has been described from deep-water hardgrounds during Mid-Cretaceous times in Spain (Reitner et al., 1995) (Figure 2). In this case, a previous benthic community dominated by coralline sponges was replaced by thick limonitic stromatolites with encrusting foraminifera and colonies of *Frutexites*.

The growth of *Frutexites* within the sediment was firstly pointed out by Böhm and Brachert (1993). They described the changes in composition and shapes of

Frutexites as a result of their growth in open spaces or in interstitial environments. Mamet and Pr  at (2006) found *Frutexites* associated to other hematite microstructures in condensed Griotte facies (Coumiac Limestones, Montagne Noire, Baleas Limestone Spain) and Rosso Ammonitico Limestone (Subbetic Cordillera Spain).

Continental environments

Some authors (Myrow and Coniglio, 1991; B  hm and Brachert, 1993) have compared the marine records of *Frutexites* with similar arborescent, dendritic forms found in speleothems, desert varnish, and travertines. Also, continental manganese and iron-rich black shrubs have been compared with the marine *Frutexites* records (Koban and Schweigert, 1993; Chafetz et al., 1998). Shapes, sizes, and polymineral character are similar in both marine and continental records.

Subterranean environments

Frutexites structures are sometimes common in light-independent, deep continental caves, fractures, and veins forming small microbial crusts often associated with calcareous stromatolitic structures. A characteristic representative was found by J. Reitner in southern Namibia (Figure 2b) at the base of the Naukluft Nappe Complex (NNC), which is part of the early Cambrian Damara orogeny (Miller, 2008). The deep base of the NNC is formed by the so-called "Sole Dolomite" (Korn and Martin, 1959) which is often heavily fractured. Within these cryptic fractures *Frutexites* is very common and intergrows with calcareous stromatolitic structures. Thin-shelled freshwater type ostracodes are also abundant in this fracture system.

A modern example of *Frutexites* structures has been found in the deep tunnel of   sp   in southern Sweden (Heim et al., 2007), as part of a highly oxygenated system. Wherever groundwater drops from the tunnel ceiling, a net-like, mineralized micro-system is formed on any rock surface beneath (Figure 3). In general, the dropping system is associated to pending mineral cones which are dominated by the iron-oxidizing, chemolithotrophic bacterium *Gallionella ferruginea*.

The evolving net-like structures feature semi-solid ridges, harboring a particular, highly diverse microbial community. The cross-section of this mineralized biofilm shows laminae with *Frutexites*-like structures (Figure 4). These are mainly composed of iron hydroxides, iron oxides, and less abundant manganese oxides. Small amounts of siderite, calcite, and siliceous material occur side by side with iron and manganese oxides.

Interpretation

Holotypes of *Frutexites* spp. (*Frutexites arboriformis*, Maslov, 1960; *Frutexites microstroma*, Walter and Awramik, 1979) were originally described from stromatolites; thus, they were genetically linked to different types of cyanobacteria (Playford et al., 1976, 1984; Scytonematacean – Walter and Awramik, 1979;

Rivulariacean – Hofmann and Grotzinger, 1985; Angulocellularia group – Riding, 1991). Hofmann and Grotzinger (1985) discussed the affinity of *Frutexites* to different cyanobacteria and proposed further alternatives (purely physicochemical accretion and/or iron bacteria due to the ferruginous character of stromatolite). The occurrence of *Frutexites* in cavities, fissures, and dykes was interpreted as a cryptobiont role (Myrow and Coniglio, 1991). However, Tsien (1979) was the first suggesting a non-phototrophic character, sometimes linked to chemoheterotrophic cyanobacteria (Gischler, 1996) or to chemohetero and autotrophic bacteria (Cavalazzi et al., 2007). Böhm and Brachert (1993) emphasized the roles of *Frutexites* as a cryptobiontic as well as a cryptoendopelitic organisms (living in interstitial habitats). Based on these aspects, the authors proposed the preference of *Frutexites* for oxygen-deficient environments (dysaerobic to anaerobic conditions). Furthermore, they suggested a bacterial precursor for the formation of *Frutexites* but did not exclude a possible fungal and/or physicochemical origin. According to previous publications (Maslov, 1960; Myrow and Coniglio, 1991), Böhm and Brachert (1993) explained the ferromanganese or phosphate mineralogy of *Frutexites* as a replacement of primary carbonate mineralogy. However, a primary iron mineralization of *Frutexites* was postulated by Horodyski (1975) and Hurley and Van der Voo (1990). Others like Hofmann and Grotzinger (1985) believed that microbiota involved in *Frutexites* could regulate the local water chemistry and iron oxyhydroxides as well as aragonite could coprecipitate.

Finally, the occurrence of *Frutexites* in condensed pelagic limestones and hardgrounds has been linked to a physicochemical origin (Wendt, 1969) as well as to iron bacteria (Reitner et al., 1995; Mamet and Pr  at, 2006). Reitner et al. (1995) interpreted the *Frutexites*–foraminifer assemblage as an R-strategic community which replaced the previous K-strategic community (sponges–microbes) due to fundamental changes in oceanographic conditions (from oligotrophic to more eutrophic conditions). Mamet and Pr  at discussed the origin of red pigmentation in some Phanerozoic limestones, where some condensed pelagic limestones with *Frutexites* are included. They argued that under anoxic to dysoxic conditions, ferrous iron may be available for oxidation by microaerophilic iron microbes growing at the sediment–water interface. In contrast, the recent *Frutexites*-like structures found in the deep biosphere in fact grow in air-exposed environments under aerobic conditions. However, the presence of different mineral phases within these structures could be associated to changing redox conditions and/or to a different microbial community composition at micrometer-range.

Conclusions

The different modes of growth of *Frutexites* have been recognized within shallow to deep water stromatolites,

on the seawater–sediment interface, marine micritic sediments, continental cavities, and fractures of deep subterranean environments. Such wider environmental distribution has been taken into consideration for paleoecological interpretations. According to the occurrence of *Frutexites*, some general aspects can be summarized: (a) its distribution does not show bathymetric control (although the dominant record is in deep waters facies), (b) it is formed in environments with very low sedimentation rate (in quiet as well as in agitated waters), (c) in marine environments, *Frutexites* mainly encrusts heterozoan assemblages (crinoids, sponges, solitary corals, and foraminifers), and finally, (d) there is no proof for an exclusive occurrence of *Frutexites* under anoxic and aphotic conditions.

Most of the authors considered a bacterially induced origin for *Frutexites*, but the final assessment strongly depends on which mineralogical composition they interpreted as primary (timing of iron mineralization) as well as its *loci* of growth.

FUNGI AND LICHENS

Bettina Weber, Burkhard B  del
 University of Kaiserslautern, Kaiserslautern, Germany

Definition

Fungi. Saprophytic, parasitic, or symbiotic living organisms, mainly filamentous (hyphae), rarely unicellular. Cell walls are of chitin or other non-cellulose compounds.
Lichens. Symbiotic organisms composed of a fungal partner, the mycobiont, and one or more photosynthetic partners, the photobiont.

Characteristics

Fungi

Fungi are a group of eukaryotic, heterotrophic organisms with their thallus on or in the substratum. The thallus can be unicellular (rarely) or filamentous (mostly), the latter being either composed of septate or nonseptate hyphae and often forming a more or less defined web of filaments (mycelium). The cell wall is typically chitinized or composed of other non-cellulose compounds. The spore forming thallus (sporocarp) can be microscopic or macroscopic with limited tissue differentiation. Fungi are cosmopolitan and ubiquitous, saprotrophic, mutualistic (mycorrhizal, lichen-forming), or parasitic. A number of rock-inhabiting fungi belong to the Deuteromycetes, a heterogenic group of fungi that develop no or only asexual sporocarp types. The vast majority of rock fungi are dark brown to blackish pigmented and are filamentous or forming microcolonies (B  del et al., 2000).

Lichens

Symbiotic mode of living

Lichens are mutualistic organisms consisting of a fungal partner, the mycobiont, and of one or more photosynthetic partners, the photobiont. Taxonomically speaking, they belong to the kingdom of fungi and represent here a special group, the lichenized fungi (Honegger, 1996). The lichen-forming fungi are polyphyletic, meaning that they have developed several times during the evolution of fungi. This brought about a taxonomically heterogeneous group with the large majority of them belonging to the Ascomycetes and only few Basidiomycetes and Deuteromycetes (= Fungi Imperfecti; Nash III, 1996a, Miadlikowska et al., 2006).

As photobiont of lichens, green algae with the most frequent genera *Trebouxia* and *Trentepohlia* make up about 90% of the photosynthetic partners, whereas cyanobacteria with the prevalent genus *Nostoc* account for the remaining 10%. The green algae, also referred to as “chlorobionts” (Lange and Wagenitz, 2003), belong to the eucaryotic algae which share many cytological features and their pigmentation (e.g., chlorophylls a and b) with land plants (Bold and Wynne, 1985; van den Hoek et al., 1993). Cyanobacteria (“cyanobionts”) are of

 University of Kaiserslautern, Kaiserslautern, Germany

Definition

Fungi. Saprophytic, parasitic, or symbiotic living organisms, mainly filamentous (hyphae), rarely unicellular. Cell walls are of chitin or other non-cellulose compounds.
Lichens. Symbiotic organisms composed of a fungal partner, the mycobiont, and one or more photosynthetic partners, the photobiont.

Characteristics

Fungi

Fungi are a group of eukaryotic, heterotrophic organisms with their thallus on or in the substratum. The thallus can be unicellular (rarely) or filamentous (mostly), the latter being either composed of septate or nonseptate hyphae and often forming a more or less defined web of filaments (mycelium). The cell wall is typically chitinized or composed of other non-cellulose compounds. The spore forming thallus (sporocarp) can be microscopic or macroscopic with limited tissue differentiation. Fungi are cosmopolitan and ubiquitous, saprotrophic, mutualistic (mycorrhizal, lichen-forming), or parasitic. A number of rock-inhabiting fungi belong to the Deuteromycetes, a heterogenic group of fungi that develop no or only asexual sporocarp types. The vast majority of rock fungi are dark brown to blackish pigmented and are filamentous or forming microcolonies (B  del et al., 2000).

Lichens

Symbiotic mode of living

Lichens are mutualistic organisms consisting of a fungal partner, the mycobiont, and of one or more photosynthetic partners, the photobiont. Taxonomically speaking, they belong to the kingdom of fungi and represent here a special group, the lichenized fungi (Honegger, 1996). The lichen-forming fungi are polyphyletic, meaning that they have developed several times during the evolution of fungi. This brought about a taxonomically heterogeneous group with the large majority of them belonging to the Ascomycetes and only few Basidiomycetes and Deuteromycetes (= Fungi Imperfecti; Nash III, 1996a, Miadlikowska et al., 2006).

As photobiont of lichens, green algae with the most frequent genera *Trebouxia* and *Trentepohlia* make up about 90% of the photosynthetic partners, whereas cyanobacteria with the prevalent genus *Nostoc* account for the remaining 10%. The green algae, also referred to as ‘‘chlorobionts’’ (Lange and Wagenitz, 2003), belong to the eucaryotic algae which share many cytological features and their pigmentation (e.g., chlorophylls a and b) with land plants (Bold and Wynne, 1985; van den Hoek et al., 1993). Cyanobacteria (‘‘cyanobionts’’) are of

procaryotic nature, lacking a nucleus, mitochondria and chloroplasts, all of which are found in eucaryotic cells. The DNA, which in eucaryotic cells is stored within the nucleus, is found as circular DNA in the cytoplasm and also the thylacoids, which occur in the chloroplasts of eucaryotes, are here embedded into the cytoplasm (Friedl and Büdel, 2008).

The interactions between the mycobiont and photobiont are not completely balanced. There is metabolic transport from the autotrophic photobiont to the heterotrophic mycobiont in the form of carbohydrates, which passively leak from the photobiont cells. Metabolic transport processes from the mycobiont to the photobiont are not known (Schöller and Mollenhauer, 1997). However, the photobiont often also profits from growth within the mycelium of hyphae, since more balanced water and light conditions are granted within the thallus. Besides that, the mycobionts produce a variety of secondary substances that might be beneficial for the photobiont (Schöller and Mollenhauer, 1997). Therefore, the lichenization of the photobiont is probably most adequately described as a controlled parasitism by lichen-forming fungi (Ahmadjian, 1993).

The thallus of a lichen is formed by a more or less dense network of fungal hyphae, in which the photobionts are either evenly distributed (homoiomorous thalli), or are concentrated within a defined layer (heteromorous thalli). Homoiomorous thallus construction mainly occurs in gelatinous, crustose lichens (e.g., *Collema*, *Pyrenopsis*) whereas heteromorous thallus construction is typically formed by an upper cortex followed by a photobiont layer, a medulla and a lower cortex (Büdel and Scheidegger, 2008). A surface tissue, like the epidermis with stomata and a protective cuticle as in higher plants, does not exist in lichens, neither do they have water and nutrient-transporting structures.

Lichen morphology

The appearance of a lichen thallus is determined primarily by the mycobiont and only in few cases the photobiont determines, to a certain extent, the form of a thallus (e.g., in the filamentous genera *Coenogonium*, *Ephebe*, *Cystocoleus*, and *Rhacodium*). However, only after the establishment of the symbiosis, under the influence of the photobiont, the characteristic thallus of a lichen is developed (Büdel and Scheidegger, 2008).

Based on their overall growth form, lichens are traditionally divided into three main morphological types: crustose, foliose, and fruticose. Crustose lichens are tightly attached to the substrate with their lower surface and cannot be removed without destruction of the thallus. Foliose lichens form leaf-like thalli that are partly attached to the substrate and have a dorsiventral organization (Büdel and Scheidegger, 2008). Thallus lobes of fruticose lichens are hairlike, strap-shaped, flat, or cylindrical, forming erect or hanging thalli. Some fruticose genera like *Baeomyces* and *Cladonia* develop a twofold thallus with

a foliose horizontal and a fruticose vertical thallus part. Endolithic lichens represent a special form of crustose lichens, where the thallus partly or completely grows within the rock. According to Golubic et al. (1981), the endolithic growth form can be further separated into cryptoendolithic (= growing within the rock), chasmoendolithic (= growing along cracks or fissures of the rock), and euendolithic (= actively boring into the rock) organisms.

Diversity

Fungi

Rock-inhabiting fungi belong to major groups of fungi: the hyphomycetes and the “black fungi,” the latter named because of the strong production of melanoid pigments that causes dark-brown or blackish pigmented hyphae. Formation of microcolonies is a universal feature of the latter group, and they are therefore named “microcolonial fungi” (= MCF; Figure 1f and i; Gorbushina, 2003). Hyphomycetes form a mycelium but lack a sporocarp and the conidia (asexual spores) are borne on hyphae. They occur on soil or epiphytic habitats and dominate on rock surfaces under milder climate regimes (e.g., high air humidity, abundant nutrients). The black MCF prevail under harsh climatic conditions and are slow-growing. They represent a diverse assemblage of non-lichenized ascomycetes. Because of a convergent microcolonial morphology and their morphological plasticity, they are extremely difficult to identify by classical methods. Identification procedures based on molecular methods are just in progress and have been applied to a few strains only. So far, identified samples and strains have been placed in the mostly anamorphic (asexual) genera *Alternaria*, *Chaetomium*, *Cladosporium*, *Coniosporium*, *Cryomyces*, *Friedmanniomyces*, *Lichenothelia*, *Phaeococcomyces*, *Phaeosclera*, *Phoma*, *Sarcinomyces*, and *Scolecobasidium* (Sigler et al., 1981; Diakumaku et al., 1995; Wollenzien et al., 1997; Sterflinger et al., 1997; Büdel et al., 2000; Selbmann et al., 2005; Onofri et al., 2007). Most of them belong to the ascomycete order Pleosporales, Capnodiales, and Dothideales, summarized in the class Dothideomycetes (Schoch et al., 2006), few belong to the Chaetothyriales in the class Eurotiomycetes (Geiser et al., 2006).

Lichens

Lichens grow on a wide variety of substrates including rocks (= epi- or endolithic), soil (= epigeic), detritus, and the branches, stems (= epiphytic), and leaves of trees (= epiphyllic). Most lichen species are specialized to one type of substrate comprising certain habitat characteristics. There are species with a wide ecological amplitude (euryoecious as compared to stenoecious species), able to colonize different types of substrate, like e.g., *Caloplaca citrina* (Hoffm.) Th.Fr., *Candelariella vitellina* (Hoffm.) Müll.Arg., and *Physcia adscendens* (Fr.) Oliv.,

Fungi and Lichens, Figure 1 (a) Granite inselberg at Soebatsfontein, Succulent Karoo, South Africa. (f) Endolithic lecidoid lichen, thallus parts visible; where the rock surface was removed (arrows), the sporocarps (fruit bodies) are exposed on the rock surface (fb); MCF indicates the presence of numerous microcolonial fungi. (g) Microscopical view on a part of the algal layer of the endolithic lecidoid lichen showing the *Trebouxia*-like chlorobionts in an envelope of lichen hyphae. (h) Colonies of the red-sheathed cyanobacterium *Gloeocapsa* sp. growing on the rock surface between the lichens. (i) Microcolonial fungi on the rock surface.

and there are nutrient-tolerant species that occur epiphytically as well as epilithically (Figure 2b and c; Wirth, 1995).

On soils, lichens often represent part of a biological soil crust (BSC). BSC are formed by an association between soil particles and different proportions of cyanobacteria, algae, microfungi, bryophytes, and lichens (Belnap et al., 2003). In arid and semiarid regions, which make up more than 30% of the land surface of the earth, BSC cover up to 25% of the soil surface (Weber et al., 2008), but also in temperate regions like Central Europe, BSC occur in various habitats (Büdel, 2003).

Rock-inhabiting lichens come from most taxonomic groups of lichens as, for example, members of the class Lichinomycetes (e.g., *Anema*, *Digitothyrea*, *Heppia*, *Lichinella*, *Peccania*, *Peltula*, *Phyllisciella*, *Synalissa*, *Thyrea*; Figure 1b–e) that exclusively have cyanobacteria as photobionts. Although these lichens can be most abundant in arid and semiarid landscapes, the vast majority of lichens (more than 200 species) come from the largest class of lichenized fungi, the Lecanoromycetes. Within the Lecanoromycetes, green algal photobionts dominate (e.g., *Acarospora*, *Buellia*, *Caloplaca*, *Dermatiscum*, *Dimelaena*, *Hymenelia*,

Fungi and Lichens, Figure 2 (a) Vegetation pattern of lichens on a natural rock surface (dolomite, Untersberg, Austria). *Hymenelia coerulea* (grayish blue areas), *Hymenelia prevostii* (white, arrows), both endolithic growing lichens. Lecidea, *Lecanora*, *Lepraria*, *Rinodina*, *Parmelia*, *Parmotrema*, *Usnea*, *Verrucaria*, *Xanthoparmelia*; Figure 2a).

Apart from natural habitats, lichens also grow on artificial substrates like mortar and building stone (Figure 2b and c; e.g., Ariño and Saiz-Jimenez, 1996; Weber and Büdel, 2001), wooden material like fences and benches, and even glass, bone, tyres, and metal under favorable climatic conditions (Schöller, 1997).

Biogeography

Fungi

Since determination on the species level is a challenging task and not easily possible without culturing or before more molecular data are available, biogeographical information is very limited at present. For some species of the genus *Lichenothelia*, however, information on distribution patterns are available. While *L. intermedia* occurs on almost every granite rock surface throughout Africa, the species *L. gigantea* and *L. radiata* are restricted to Australia, and *L. globulifera* was only found on rock outcrops of the Seychelle island La Digue (Henssen 1987). On the basis of morphological and molecular data (SSU phylogeny and ITS sequence data), Selbmann et al. (2005) recently described two new genera of MCF, *Cryomyces*, and *Friedmanniomyces*, only known from Antarctic rocks so far. The authors provide good evidence that at least the new genus *Cryomyces* might be endemic to Antarctica. Since MCF diaspores are easily spread over large distances by the wind, many of them might have a cosmopolitan distribution (airborne fungi).

Lichens

Lichens have developed during evolutionary radiation of ascomycete fungi within the last 600–400 million years, possibly contemporaneous to the emergence of land plants (Galloway, 1996). Due to this long-lasting evolutionary process, their distribution patterns show similarities to other groups of organisms and can be explained utilizing the theory of plate tectonics (Galloway, 1996). Compared to vascular plants, lichens comprise a higher number of cosmopolitan species within different climate zones of the earth and endemism within smaller geographic regions is normally lower. Exemplarily, on the Kap Verde Islands 13.4% of vascular plants were endemics, whereas only 2.5% of the lichen species were found to be endemic (Schöller, 1997). Dispersal of both symbiotic partners is facilitated by the fact that fungal spores as well as algal cells are transported over vast distances within the air (Brown et al., 1964).

At least 16 major distribution patterns of lichens can be distinguished (Galloway, 1996). Besides lichen species that are constrained to one single continent, like austral and neotropical taxa, there are distribution patterns that comprise spatially contiguous regions, like the paleotropics that include most of Africa, the Arabian Peninsula, most of the Indian subcontinent, the Malaysian archipelago, and the Islands of the Pacific Ocean (Galloway, 1996). A third type of distribution pattern embraces disjunct distributions over continents, which have been close by or unified in history, but were separated by plate tectonic movements, like pantropical and American–Asian distribution patterns (Grotzinger et al., 2006). Taxa with bipolar distribution represent the last pattern, which results from climate change through earth history. These organisms occur at high latitudes of the

northern and southern hemisphere, but often also occur in alpine regions, forming relict habitats of the last ice age (Galloway, 1996).

Physiology

Fungi

There is not much known of the specific physiology of rock-inhabiting fungi except that they are able to tolerate extremely high (70–80°C; Palmer et al., 1987) and low temperatures (–40°C; Selbmann et al., 2005) due to their poikilohydric nature and related to that, their ability to withstand long periods (in the magnitude of tens of years) in the dry state. Many fungi are heavily melanized, most probably as a shelter against high radiation of both visible and UV light.

Lichens

Lichens are poikilohydric organisms, meaning that they cannot actively take up or lose water. Moistening of the thallus can be achieved by rain/snow precipitation, dew-fall, and equilibrium with high air humidity. This clearly distinguishes them from vascular plants that actively regulate water uptake and loss.

Water

Although water uptake, storage, and loss are modified by differences in thallus structure and morphology, these mechanisms are predominantly controlled by physical processes (Rundel, 1988). Therefore, the physiological activity of lichens is highly dependent on the prevailing water conditions. In general, the photosynthetic response of lichens to increasing water content can be described as an optimum curve, which, however, reveals large variability (Lange et al., 2001). Air-dried lichens with a water content below 15–30% show no photosynthetic response at all (Nash III, 1996b). With increasing water content, lichens first reveal net respiration rates before the compensation point is reached, above which positive photosynthetic activity is recorded. In general, cyanolichens commence positive net photosynthesis (NP) at higher water contents and are generally able to perform positive NP under higher water content than chlorolichens (especially the homoiomerous species; Lange et al., 2001).

Above an optimum water content, at which maximum NP rates are reached, free water is present and the lichens have a water potential close to zero (Green and Snelgar, 1982). These periods of water supra-saturation cause a depression in photosynthesis by increased thallus diffusive resistances; CO₂ pathways within the thallus are blocked by water (Lange et al., 1997). Water supra-saturation can occur in chloro- and cyanolichens of all growth forms (Lange et al., 1996, 2000, 2004; Lange and Green, 1997), and also endolithic lichens of various substrates have to cope with this problem (Tretiach and Pecchiari, 1995; Tretiach and Geletti, 1997; Winkler and Kappen, 1997). In a recent study, the photosynthetic

performance of *Hymenelia prevostii* and *H. coerulea*, two endolithic green algal lichens growing on steep limestone outcrops in the eastern alpine mountains, have been investigated in detail (Weber et al., 2007). Both species were saturated at extremely low water content (*H. prevostii*: 0.26 mm, *H. coerulea*: 0.07 mm rainfall equivalent) and revealed very narrow ranges of positive NP values upon increasing thallus water content (0.2 mm vs. 0.1 mm). Their growth on steep rock surfaces therefore represents an adaptation to avoid excessively high water contents or the formation of CO₂ blocking water films.

A crucial difference in the physiology of cyano- and chlorolichens lies in the capability to use water vapor for photosynthetic activation. While air-dry chlorolichens gain positive NP in equilibrium with air of about 80% relative humidity and above, all cyanobacterial lichens investigated so far need liquid water for activation of NP (Büdel and Lange, 1991; Lange et al., 1993). This fundamental difference also affects the natural habitats of lichens with cyanolichens preferably occurring at moist habitats with frequent liquid water (e.g., *Collema* spp., *Lichinella* spp.), whereas green algal lichens often also occur in rain-shaded habitats of high air humidity (e.g., *Lepraria* spp., *Usnea* spp.). The endolithic *Hymenelia* species mentioned above were also shown to perform positive NP at relative air humidities of 90% and above (Weber et al., 2007).

Light

The capture of radiant energy is essential for photosynthesis. Only light of wavelengths between 400 and 780 nm, the photosynthetically active radiation (PAR), is utilized for photosynthesis (Nash III, 1996b). Under constant and favorable abiotic conditions, photosynthetic response of lichens to increasing light intensities exhibits a saturation curve with saturation for most species occurring between 100 and 400 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Demmig-Adams et al., 1990). However, extremely shade-tolerant species have saturation values as low as 20 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Green et al., 1991), whereas others, like *Ramalina maciformis* (Del.) Bory reveal values above 1,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (Demmig-Adams et al., 1990). At increasing temperatures, light saturation is achieved at higher levels (Kershaw, 1985) and also water content has an influence (Lange, 1969), probably due to alterations of light penetration within the thallus (Ertl, 1951; Dietz et al., 2000). Exposure of fully hydrated lichens to excess light can induce a depression of photosynthesis, both in chloro- and cyanolichens (Demmig-Adams et al., 1990).

As a protection against excessive light, lichens in general possess a cortex made of fungal tissue, and some species even form a so-called epinecral layer consisting of dead, collapsed, and often gelatinized hyphae and photobiont cells (Büdel and Scheidegger, 2008). *Peltigera rufescens* (Weiss) Humb., for example, has a cortical organization that causes a decrease of light transmittance to

40% at the upper boundary of the algal layer (Dietz et al., 2000).

The endolithic growth form (Figure 1f) can also be interpreted as a protection from excess light. Winkler and Kappen (1997) found that only 0.1–0.2% of the ambient light reaches the upper part of the algal layer in *Sarcogyne* cf. *austroafricana* (Zahlbr.) H. Magn. Light reduction within the sandstone on top of the photosynthetically active layer is also reflected by light saturation values above 800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ measured for *Sarcogyne* cf. *austroafricana*, *Lecidea* aff. *sarcogynoides* Körb., *Lecidea confluenta* Müll. Arg. and *Lithoglypha aggregata* Brusse (Winkler and Kappen, 1997). In limestone, *Hymenelia prevostii* and *H. coerulea* were saturated at high light intensities (1,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ vs. 800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$; Weber et al., 2007).

Temperature

Lichens are generally known to survive a wide range of temperatures. Being dominant terrestrial organisms of Antarctica, they must be able to tolerate extremely low temperatures (Nash III, 1996b), whereas in sun-exposed microhabitats, lichens experience temperatures of up to 60°C (Hahn et al., 1989). However, lichens in general reveal a vast difference in temperature tolerance depending on whether the thalli are hydrated or dry. Whereas dry thalli of some lichen species are able to tolerate a stepwise cooling to temperatures as low as –196°C (Kappen, 1973) and heating up to 90 or 100°C (Lange, 1953), wet thalli are by far more sensitive. Review of field measurements of lichen photosynthesis revealed that many lichens are primarily active at temperatures between 5°C and 20°C, although 0–10°C may better characterize some Antarctic species (Kappen, 1988; Kappen and Friedmann, 1983).

Photosynthetic capacity of some lichen species is known to reveal seasonal changes that involve an adjustment to higher summer temperatures (Kershaw, 1985). Recently, Lange and Green (2005) proved that dark respiration (DR) of lichens does exhibit seasonal changes of temperature sensitivity. At 5°C, for example, the respiration rates of *Cladonia convoluta* (Lam.) P.Cout., *Lecanora muralis* (Schreber) Rabenh., and *Diploschistes muscorum* (Scop.) R.Sant. were several times higher in winter than in summer. This acclimation of DR implies that maximal net carbon fixation rates remain similar throughout the year and are not depressed by increased carbon loss due to higher temperatures during the warmer season (Lange and Green, 2005).

CO₂

The photosynthetic CO₂-fixation rate of lichens at optimal water content generally increases with increasing CO₂-concentrations, typically reaching saturation around 600–1,300 ppm (Nash III, 1996b; Tretiach and Geletti, 1997; Lange et al., 1999; Lange, 2002). At natural CO₂ concentrations (around 360 ppm), many species only

reach about 60–80% of maximal NP under optimal water conditions (Lange et al., 1999; Lange, 2002).

Under supra-saturated water conditions, NP of lichens is often depressed at natural CO₂ concentrations. Increased CO₂ values, however, in most cases result in attenuation of this depression (e.g., Lange, 2002). In some species, as for the epigeic species *Fulgensia fulgens* (Sw.) Elekin, a severe depression in CO₂ uptake can even be completely counterbalanced by a CO₂ concentration of 4,500 ppm (Lange et al., 1999).

The CO₂ compensation point (CO₂ concentration, at which respiration equals photosynthesis) in many lichen species is very low as compared to vascular plants (Nash III, 1996b). This often results from a CO₂ concentrating mechanism (CCM), by which CO₂ is actively pumped into the photobiont cells (Badger et al., 1993). Such a CCM is also present within the photobiont *Trebouxia irregularis* Hildreth and Ahmadjian of the endolithically growing *Hymenelia* species, which makes them less susceptible to elevated CO₂ concentrations (Weber et al., 2007).

Interactions with the substrate

Bare natural rock surfaces are extremely rare on earth and might only be found under extreme climatic conditions of hot or cold deserts. Normally, rock surfaces are covered by a dense layer (film, crust; Figure 1a) composed of cyanobacteria (Figure 1h), algae, lichens (Figure 1b–f), and fungi (Figure 1f and i). Cyanobacteria, lichens, and fungi also can grow inside the rock itself, in the upper few millimetres (= endolithic, Figure 1f and g). On inselbergs of tropical savannas, these biofilms are even responsible for the characteristic black (cyanobacteria dominated) or brown color (lichen dominated) of the rock surface (Büdel et al., 2000).

Fungi

Fungi grow on rock surfaces (epilithic), inside the rock (endolithic) or are part of the desert varnish produced by microorganisms growing inside the up to 1 cm thick black layer (e.g., Krumbein and Jens, 1981). Also MCF have been shown to be involved in desert varnish formation in Arizona and Australia (Taylor-George et al., 1983). Microbial growth on rock surfaces follows the microscopic landscape formed by mineral grains, pores, and fissures of the substratum (Figure 1f and i). Characteristically, microorganisms of the resulting biofilms colonize in the way that fungal hyphae and some cyanobacteria penetrate the substrate, while algae, bacteria, and microcolonies of yeast-like fungi clump together (Gorbushina, 2007). They secrete extracellular polymeric substances (EPS), which envelope the microcolonies, keep them together and adhere them to the substratum.

Biogenic rock weathering is surely a multifactorial process. The role of fungi in the wear-down of rocks is difficult to separate from the activity of other microorganisms of biofilms. Generally, there are two main groups of weathering that can be distinguished. (1) Either the growth of cells forces separation of mineral grains (Dornieden

et al., 1997), or desiccation/hydration cycles of cell walls and EPS cause their separation (Friedmann and Weed, 1987; Warscheid et al., 1991). (2) Dissolution of rock minerals can be achieved by organic acids released from cells, chemical impact of respiratory CO₂, H⁺, and redox reactions with metal-ions (Gadd, 1999; Burford et al., 2003).

Lichens

During the 1980s and 1990s, a huge variety of literature on the patterns and effects of biogenic weathering by lichens has been published. However, a comprehensive understanding on the overall mechanisms, effects, and magnitude of effects could not yet be accomplished (Chen et al., 2000).

As for the fungi, the impact of lichens can be subdivided into physical and chemical effects. The physical effects comprise: (1) penetration of hyphae through intergranular cavities and along mineral cleavage planes; (2) thallus expansion and contraction due to varying water content; (3) freezing and thawing of the lichen thallus; (4) swelling of organic and inorganic salts originating from lichen activity; and (5) incorporation of mineral fragments into the thallus (Chen et al., 2000).

The chemical effects comprise the solubilization and the insolubilization of inorganic elements, resulting in the weathering of minerals (silicates, phosphates, carbonates, sulfides, oxides) and the formation of new deposits (carbonates, oxides, sulfides, phosphates; Benthelin, 1988). The solubilization processes, as induced by lichens include (1) the release of metal ions by acid and complexing compounds, and (2) the acidification or alkalization by uptake or release of alkaline compounds. Insolubilization processes are oxidation of Fe²⁺ and Mn²⁺, and uptake of elements by the organisms in different environments (Benthelin, 1988).

Besides the alkalization activity of endolithic cyanobacteria (Büdel et al., 2004), it is also expected that lichens perform a similar role on/in rocks. Wessels and Schoeman (1988) describe an exfoliation process initiated by the endolithic lichen *Lecidea* aff. *sarcogynoides* Koerb. In SEM imagery, they perceived a dissolution of the binding material along the growth zone of the hyphae and also pitting marks on the quartz crystals were observed, where hyphae had attached to the surface of the crystals (Wessels and Schoeman, 1988). Besides *L. aff. sarcogynoides*, also lichens of the genus *Caloplaca* are found to contribute to rock weathering in sandstones of South Africa (Figure 2d). Friedmann (1982) and Friedmann and Weed (1987) report on cryptoendolithic microorganisms in the Antarctic cold desert (Ross Desert) being dominated by lichens that cause a exfoliative weathering pattern along the lichen growth zone very similar to the pattern described by Büdel et al. (2004).

Conclusions

Identification of lichens on the basis of their external and internal morphology, as well as chemical characteristics, is well-established and only in some cases, where lichens

do not express a typical morphology or where they are often sterile, e.g., in the endolithic habitat, additional identification methods, using a molecular approach are necessary. Thus, lichen diversity of different rock types is quite well-known. Rock-inhabiting fungi, on the other hand, are much more difficult to identify. They often only express a reduced set of morphological features, insufficient for save identifications. Here, the use of molecular techniques is a must and already lead to a considerable increase in knowledge (e.g., Selbmann et al., 2005).

The interaction of fungi and lichens with their rock substratum is manifold. Biofilms with fungi and lichens might either increase weathering rates of their substratum, or in some cases, protect it from weathering. However, these crusts and films on rocks are a complex mixture of bacteria, cyanobacteria, algae, fungi, and microlichens embedded in the common structure of an EPS. Macrolichens rising above the biofilm form a separate layer, comparable to that of emergent trees that rise above the canopy of rain forests.

Microbial biodiversity of rock surfaces and the complex interaction of these organisms among themselves and with the rock substratum, for example, their role in bioweathering, is still poorly understood at present and will surely be a field of intensive and fascinating research in future.

GALLIONELLA

Karsten Pedersen
Göteborg University, Göteborg, Sweden

Definition

Gram-negative, microaerophilic, and chemolithotrophic bean-shaped cells that secrete an extracellular twisted stalk and can grow with ferrous iron as source of energy and carbon dioxide as the sole source of carbon.

The genus *Gallionella* is characterized by its chemolithotrophic growth with ferrous iron as source of electrons and energy and carbon dioxide as source of carbon. Mixotrophic metabolism has been demonstrated with glucose, fructose, and sucrose (Hallbeck and Pedersen, 1991). The family *Gallionellaceae* has one known species, *Gallionella ferruginea* (Hallbeck et al., 1993; Hallbeck and Pedersen, 2005). The organism produces a twisted stalk that consists of a bundle of numerous organic fibers, which makes *Gallionella* very easy to identify (Figure 1). The potential functions of the stalk is to act as a holdfast (Figure 2) and possibly also to act as a sorbent for the iron oxides produced by the organism during its oxidation of ferrous iron to ferric iron. This stalk allows easy identification not only in modern systems but it also allows use as fossil to trace the activity of *Gallionellaceae* in the past. The stalk production appears to be stimulated by pH values above 6 (Hallbeck and Pedersen, 1990). Optimal growth and stalk formation under in situ conditions occur under microaerophilic conditions (0.4–1.5 mg oxygen L⁻¹) in an E_h range between +150 and +250 mV (Hallbeck and Pedersen, 1995; Anderson and Pedersen, 2003). The environment where stalk-forming *Gallionella* can be observed, commonly attached to surfaces, is slowly flowing groundwater that is rich in ferrous iron

but has low organic carbon and oxygen concentrations. Typical places to find *Gallionella* are in drain pipes, storage basins for groundwater from deep wells, in tunnels, and on rock walls with seeping groundwater. Colonies of *Gallionella* rapidly develop to visible structures in

Gallionella, Figure 1 *Gallionella ferruginea* produces a twisted stalk that consists of numerous thin organic fibers. As the stalks age, iron oxides precipitate on the stalks and many trace elements co-precipitate (Anderson and Pedersen, 2003). The attachment of the cell to the stalk is very brittle and they are, therefore, commonly detached during the preparation of specimens for the microscope. Diameter of the stalks is typically 0.3–0.5 µm in width and up to 400 µm or more in length. Photo: Karsten Pedersen.

Gallionella, Figure 2 Colonies of *Gallionella ferruginea* growing in a shallow pond. The twisted stalks make their way up through the water. In this way, they reach the energy-rich ferrous iron in the water, while escaping the waste they produce, iron oxides. Diameter of the moss-like colonies was 1–2 cm. Photo: Karsten Pedersen.

water (Figure 2). Growth of *Gallionella* in groundwater seeping out from fractures in rock walls develops to compact mats of cells, stalks, and iron oxides. Such mats can reach a thickness of several centimeters in less than a year and they may enrich trace elements up to 10^6 times their respective concentrations in the seeping groundwater (Anderson and Pedersen, 2003).

GEOBACTER

Kristina L. Straub
 University of Vienna, Vienna, Austria

Definition

Geobacter is the name of a genus that is located within the *Deltaproteobacteria* comprising several species of Fe(III)-reducing bacteria (Lovley et al., 1993). The genus *Geobacter* represents the type genus of the family Geobacteraceae which includes also the genera *Desulfuromonas*, *Desulfuromusa*, *Geoalkalibacter*, *Geopsychrobacter*, *Geothermobacter*, *Malonomonas*, and *Pelobacter*.

The type species of the genus *Geobacter* is *Geobacter metallireducens* strain GS-15, which was enriched and isolated from pristine freshwater sediments of the Potomac River with acetate as the electron donor and poorly crystalline ferric iron as the electron acceptor. In addition to pristine aquatic habitats, *Geobacter* species were isolated from deep aquifer sediments (e.g., *G. chapellei*), subsurface sediments (e.g., *G. bemidjensis*), or various contaminated sites (e.g., *G. sulfurreducens*). Cells of *Geobacter* species stain Gram-negative and are non-spore-forming. All *Geobacter* species have midrange temperature optima (25–35°C) and grow only under strictly anoxic conditions. Alternative electron acceptors for *Geobacter* species include nitrate, elemental sulfur, fumarate, malate, Mn (IV), U(VI), Co(III), anthraquinone-2,6-disulfonic acid,

Definition

Cyanobacteria are a large and morphologically rather diverse group of photoautotrophic prokaryotes and are classified as a monophyletic phylum within Domain Bacteria. Cyanobacteria share oxygenic photosynthesis with the eukaryotic algae. Cyanobacteria belong to the oldest organisms on earth. Their broad environmental tolerance range makes cyanobacteria well suited to live in habitats of extreme and fluctuating conditions where they can outcompete eukaryotic algae.

Many cyanobacteria have large cells like the eukaryotic algae with which they share the same life-style: Consequently, they are often treated as prokaryotic algae or, formerly, blue-green algae. Some cyanobacteria even form macroscopic colonies from the size of a few millimeters to up to 30 cm (Dodds and Castenholz, 1988). Cyanobacteria occur in a broad variety of forms, from solitary unicells over colony-forming and undifferentiated filamentous types to more complex forms that even display the hallmarks of multicellularity. Photosynthetic cyanobacteria produced earth's first oxygen atmosphere, which fostered the rise of eukaryotes. In addition, ancient cyanobacteria produced massive undersea carbonate deposits, thereby reducing atmospheric carbon dioxide levels and influencing global climate. The first plastids arose from cyanobacteria through a process called primary endosymbiosis (McFadden, 2001; Keeling, 2004; Palmer, 2003; Reyes-Prieto et al., 2007). Modern cyanobacteria are recognized for their ability to occupy diverse aquatic and terrestrial habitats, cyanobacteria produce organic compounds used by other organisms, and they stabilize sediments and soils. Nitrogen-fixing cyanobacteria increase soil and water fertility and foster the growth of certain plants and fungi in symbiotic associations. There is strong evidence that cyanobacteria are the oldest microorganisms performing oxygenic photosynthesis, dating back to about 2.45 billion years (Rasmussen and Willemotte, 2008) and with an evolutionary history stretching over at least 1.5 and possibly 2.7 billion years (Blank, 2004). Cyanobacteria are able to live in some of the most extreme habitats on earth (e.g., Seckbach, 2007 for an overview). The broad environmental tolerance range of cyanobacteria in extreme habitats is in contrast to most other prokaryotic and eukaryotic organisms from extreme environments that occur only within a small window of almost constant conditions. From an evolutionary point of view, it appears that cyanobacteria which are

Definition

Geobacter is the name of a genus that is located within the *Deltaproteobacteria* comprising several species of Fe(III)-reducing bacteria (Lovley et al., 1993). The genus *Geobacter* represents the type genus of the family Geobacteraceae which includes also the genera *Desulfuromonas*, *Desulfuromusa*, *Geoalkalibacter*, *Geopsychrobacter*, *Geothermobacter*, *Malonomonas*, and *Pelobacter*.

The type species of the genus *Geobacter* is *Geobacter metallireducens* strain GS-15, which was enriched and isolated from pristine freshwater sediments of the Potomac River with acetate as the electron donor and poorly crystalline ferric iron as the electron acceptor. In addition to pristine aquatic habitats, *Geobacter* species were isolated from deep aquifer sediments (e.g., *G. chapellei*), subsurface sediments (e.g., *G. bemidjensis*), or various contaminated sites (e.g., *G. sulfurreducens*). Cells of *Geobacter* species stain Gram-negative and are non-spore-forming. All *Geobacter* species have midrange temperature optima (25–35°C) and grow only under strictly anoxic conditions. Alternative electron acceptors for *Geobacter* species include nitrate, elemental sulfur, fumarate, malate, Mn (IV), U(VI), Co(III), anthraquinone-2,6-disulfonic acid,

and humics. Furthermore, *G. metallireducens*, *G. psychrophilus*, and *G. sulfurreducens* were shown to transfer electrons from the oxidation of organic compounds onto the surface of electrodes. All *Geobacter* species utilize acetate as electron donor and carbon source; other electron donors that are utilized by the majority of *Geobacter* species include ethanol, pyruvate, lactate, hydrogen, and formate. *Geobacter* species are unable to grow by fermentation. Ecological studies indicate that *Geobacter* species predominate under iron-reducing conditions. Furthermore, the combination of ecological and physiological studies implies that *Geobacter* species might play important roles in bioremediation processes such as the oxidation of aromatic compounds, the reduction of tetrachloroethene, or the immobilization of U(VI).

Species: *G. argillaceus*, *G. bemidjensis*, *G. bremensis*, *G. chapellei*, *G. grbiciae*, *G. humireducens*, *G. hydrogenophilus*, *G. lovleyi*, *G. metallireducens*, *G. pelophilus*, *G. pickeringii*, *G. psychrophilus*, *G. sulfurreducens*, *G. thiogenes*, *G. uraniireducens*

Among the validly described *Geobacter* species, *G. metallireducens* strain GS-15 and *G. sulfurreducens* strain PCA are the most intensively studied in terms of physiology, biochemistry, and genetics. The genomes of both species were sequenced and a genetic system was established for *G. sulfurreducens* (Méthé et al., 2003).

GEOCHRONOLOGY

Volker Liebetrau
Leibniz Institute of Marine Sciences, IFM-GEOMAR,
Kiel, Germany

Synonyms

Age determination; Dating

Definition

Geochronology. Determination of ages and time intervals for geologic materials and processes on geologic, archeologic, and historic time scales. The science of investigating and reflecting the chronology of the earth constituents as induced from geologic data, based on absolute and relative dating methods.

Age, absolute. Age determination based on radioactive elements, their rates of decay and physical measurements, resulting in an actual age given in years for the analyzed geologic material (e.g., mineral, rock, fossil, fluid).

Age, relative. Age information based on stratigraphic anomalies (e.g., lithostratigraphic and biostratigraphic principles, field observations) or utilizing chemical reaction rates (e.g., diffusion, exchange, oxidation, hydration) as a measure of time.

Units. Geochronologic data are presented as yr BP (years before present), as ka (age date in thousands of years), as kyr (time interval in thousands of years, e.g., between distinct age data), following the same principle as Ma and Myr (millions of years), respectively. Alternatively, the mathematical expression in years, times order of magnitude is used and favored for age data and time intervals in the range of billions of years and the description of half-lives (e.g., 4.47×10^9 years, half-life of the ^{238}U isotope).

Introduction

The term “geochronology” may reasonably be used in reference to all principles and methods employed in geology to determine the relative and numerical ages of all kinds of rocks (Walsh, 2001). The immense age of the Earth and the long-term duration of processes changing the morphology and composition of the Earth’s crust and interior were progressively recognized throughout the last centuries. Geoscientists developed and established a relative chronological systematic based on lithostratigraphic and biostratigraphic principles, including global correlations and ongoing refinement. The actual state of the art is presented by the International Commission on Stratigraphy (ICS, 2009; <http://www.stratigraphy.org/upload/ISChart2009.pdf>).

In contrast, the direct determination of absolute ages required fundamental new physical approaches and analytical methods in the field of geochemistry. The basis for “geochronology” as a new geoscientific discipline was provided by the early description of radioactive transformations more than 100 years ago (Rutherford, 1906). An actual status in combining detailed knowledge of relative age successions with precise absolute ages and the impact of resulting chronostratigraphy on the understanding of the Earth’s geologic evolution is presented in concise manner by Ogg et al. (2008). A still valid and systematic overview about the broad variety, principles, scopes, potentials, and limitations of physical and chemical dating methods is given in a comprehensive way by Geyh and Schleicher (1990). This work is especially

ICP-MS. Unfortunately, this in situ approach is still hampered by the high uncertainties of low-counting statistics on samples younger than 10 ka. Meanwhile, recent efforts in conventional data precision and sample selection pushed the maximum limit of age determination with the U-Th method to the successful dating of extraordinarily well preserved 600-ka-old corals (Andersen et al., 2008).

Summary

Geochronology in geobiologic approaches offers detailed insights into the time scales of biological processes, changes in biochemical fluxes, and the identification of driving mechanisms. Still open challenges are the rather low sample throughput of conventional clean-lab preparation procedures, the necessary achievements in precision for in situ approaches, and the methodical extension toward reliable dating tools covering the last millions of years.

Definition

Geomycology. The scientific study of the roles of fungi in processes of fundamental importance to geology

Introduction

Fungi are chemoorganotrophic (heterotrophic) organisms relying on organic carbon sources for energy and metabolism, and ubiquitous in aquatic and terrestrial environments. They are important as decomposers, animal and plant mutualistic symbionts and pathogens, and spoilage organisms of natural and manufactured materials (Gadd, 1993a, 1999, 2006; Burford et al., 2003a). They also have a role in the maintenance of soil structure due to their predominantly filamentous branching growth habit (each filament is called a hypha; plural = hyphae; all the hyphae constitute the mycelium) and frequent exopolymer production. Fungi have important roles in the biogeochemical cycling of the elements (e.g., C, N, P, S, metals), and this is linked with their ability to adopt a variety of growth, metabolic, and morphological strategies, their adaptive capabilities to environmental extremes and, their mutualistic associations with animals, plants, algae, and cyanobacteria (Gadd and Griffiths, 1980; Burford et al., 2003a; Gadd, 2004a, 2007a, b; Braissant et al., 2004; Gadd et al., 1984, 2005; Fomina et al., 2005a, 2006a, b) (Table 1). Fungal polymorphism and reproduction by huge numbers of spores underpins successful colonization of many different environments. Most fungi exhibit a filamentous growth habit which enables explorative or exploitative growth strategies, and many form linear organs of aggregated hyphae for protected translocation of nutrients (Jacobs et al., 2002, 2004; Boswell et al., 2002, 2003, 2006; Fomina et al., 2005a, b). Some fungi are polymorphic, occurring as both filamentous mycelium and unicellular yeasts or yeast-like cells, as in the black microcolonial fungi colonizing rocks (Gadd and Griffiths, 1980; Sterflinger, 2000; Gorbushina et al., 2002a, b, 2003). Some fungi are predominantly unicellular such as the yeasts, exemplified by *Saccharomyces cerevisiae*.

A broad appreciation of fungi as agents of biogeochemical change is lacking within geobiology, and apart from obvious connections with the carbon cycle, they are frequently neglected within broader geomicrobiological and geochemical contexts. While the geochemical activities

Geomycology, Table 1 Summary of important roles and activities of fungi in geomycological processes. These may take place in aquatic and terrestrial ecosystems, as well as in artificial and man-made systems, their relative importance depending on the species and active biomass present and physicochemical factors. The terrestrial environment is the main site of fungal-mediated biogeochemical changes, especially in mineral soils and the plant root zone, decomposing vegetation, and on exposed rocks and mineral surfaces. There is rather a limited amount of knowledge on fungal geobiology in freshwater and marine systems, sediments, and the deep subsurface. In this table, fungal roles have been arbitrarily split into categories based on growth, organic and inorganic metabolism, physicochemical attributes, and symbiotic relationships. It should be noted that many if not all of these are linked, and almost all directly or indirectly depend on the mode of fungal growth (including symbiotic relationships) and accompanying chemoorganotrophic metabolism, in turn dependent on a utilizable C source for biosynthesis and energy, and other essential elements, such as N, O, P, S, and many metals, for structural and cellular components. Mineral dissolution and formation are detailed separately although these processes clearly depend on metabolic activity and growth form (adapted from Gadd, 2007a)

Fungal attribute or activity	Geomycological consequences
Growth	
Growth and mycelium development; fruiting body development; hyphal differentiation; melanization	Stabilization of soil structure Penetration of rocks and minerals Biomechanical disruption of solid substrates, building stone, cement, plaster, concrete, etc. Plant, animal and microbial colonization, symbiosis and/or infection; mycorrhizas, lichens, pathogens Nutrient and water translocation Surfaces for bacterial growth, transport, and migration Mycelium acting as a reservoir of N and/or other elements
Metabolism	
Carbon and energy metabolism	Organic matter decomposition and cycling of component elements, e.g., C, H, O, N, P, S, metals, metalloids, radionuclides Altered geochemistry of local environment, e.g., changes in redox, O ₂ , pH Production of inorganic and organic metabolites, e.g., H ⁺ , respiratory CO ₂ , organic acids, siderophores Exopolymer production Organometal formation and/or degradation Degradation of xenobiotics and other complex compounds
Inorganic nutrition	Altered distribution and cycling of inorganic nutrient elements, e.g., N, S, P, essential and inessential metals, metalloids, organometals, and radionuclides Transport, accumulation, incorporation of elements into macromolecules Redox transformations of metal(loid)s and radionuclides Translocation of water, N, P, Ca, Mg, K, etc. through mycelium and/or to plant hosts Fe(III) capture by siderophores MnO ₂ reduction Element mobilization or immobilization including metals, metalloids, radionuclides, C, P, S, etc.
Mineral dissolution	Mineral and rock bioweathering Leaching/solubilization of metals and other components, e.g., phosphate Element redistributions including transfer from terrestrial to aquatic systems Altered bioavailability of, e.g., metals, P, S, Si, and Al Altered plant and microbial nutrition or toxicity Mineral formation, e.g., carbonates, oxalates, clays Altered metal and nutrient distribution, toxicity, and bioavailability Mineral soil formation
Mineral formation	Biodeterioration of building stone, cement, plaster, concrete etc. Element immobilization including metals and radionuclides, C, P, and S Mycogenic carbonate formation Limestone calcrete cementation Mycogenic metal oxalate formation Metal detoxification Contribution to patinas on rocks (e.g., "desert varnish")
Physicochemical properties	
Sorption of soluble and particulate metal species, soil colloids, clay minerals, etc.	Altered metal distribution and bioavailability Metal detoxification Metal-loaded food source for invertebrates Prelude to secondary mineral nucleation and formation

Geomycology, Table 1 (Continued)

Fungal attribute or activity	Geomycological consequences
Exopolymer production	Complexation of cations Provision of hydrated matrix for mineral formation Enhanced adherence to substrate Clay mineral binding Stabilization of soil aggregates Matrix for bacterial growth Chemical interactions of exopolymers with mineral substrates
Symbiotic associations Mycorrhizas	Altered mobility and bioavailability of nutrient and inessential metals, N, P, S, etc. Altered C flow and transfer between plant, fungus, and rhizosphere organisms Altered plant productivity Mineral dissolution and metal and nutrient release from bound and mineral sources Altered biogeochemistry in soil-plant root region Altered microbial activity in plant root region Altered metal distributions between plant and fungus Water transport to and from the plant
Lichens	Pioneer colonizers of rocks and minerals, and other surfaces Bioweathering Mineral dissolution and/or formation Metal accumulation by dry or wet deposition, particulate entrapment, metal sorption, transport, etc. Enrichment of C, N, P, etc. in thallus and alteration of elemental concentrations and distribution in local microenvironment Early stages of mineral soil formation Development and stimulation of geochemically active microbial populations Mineral dissolution by metabolites including "lichen acids" Biomechanical disruption of substrate
Insects and invertebrates	Fungal populations in gut aid degradation of plant material Invertebrates mechanically render plant residues more amenable for decomposition Cultivation of fungal gardens by certain insects (organic matter decomposition and recycling) Transfer of fungi between plant hosts by insect vectors (aiding infection and disease)
Pathogenic effects Plant and animal pathogenicity	Plant infection and colonization Animal predation (e.g., nematodes) and infection (e.g., insects, etc.) Redistribution of elements and nutrients Increased supply of organic material for decomposition Stimulation of other geochemically active microbial populations

of bacteria and archaea receive considerable attention, especially in relation to carbon-limited and/or anaerobic environments, in aerobic terrestrial environments fungi are of great importance, especially when considering rock surfaces, soil, and the plant root–soil interface (Table 1). For example, symbiotic mycorrhizal fungi are associated with most plant species and are involved in major mineral transformations and redistributions of inorganic nutrients, e.g., essential metals and phosphate, as well as carbon flow (Fomina and Gadd, 2007) (Figure 1). Free-living fungi have major roles in the decomposition of plant and other organic materials, including xenobiotics, as well as in mineral solubilization. Lichens (a fungal growth form comprising a mutualistic symbiosis between an alga and/

or cyanobacterium and a fungus) commonly inhabit exposed rock (and other) substrates, and play fundamental roles in early stages of rock colonization and mineral soil formation (Haas and Purvis, 2006). Fungi are also major biodeterioration agents of stone, wood, plaster, cement, and other building materials, and they are important components of the rock-inhabiting microbial communities with involvement in mineral dissolution and secondary mineral formation (Burford et al., 2003a, b, 2006; Fomina et al., 2005a, b; Gadd, 2007a; Gadd et al., 2005, 2007).

The earliest fossil filamentous fungal remains appear to be from the mid- to late Precambrian (1430–1542 Myr ago), and they were extremely diverse by Devonian times, when forms belonging to major groups and even some

Geomycology, Figure 1 Simple model of fungal action on naturally occurring and/or anthropogenically derived organic and inorganic substrates. (1) organic and inorganic transformations mediated by enzymes and metabolites, e.g., H^+ , CO_2 , and organic acids, and physicochemical changes occurring as a result of metabolism; (2) uptake, metabolism, or degradation of organic substrates; (3) uptake, accumulation, sorption, metabolism, or degradation of inorganic substrates; (4) biosynthesis and production of organic metabolites, exopolymers, macromolecules, and biomass; (5) production of inorganic metabolites, secondary minerals, and transformed (organo)metal(loid)s; and (6) chemical interactions between organic and inorganic substances, e.g., complexation and chelation. (Adapted from Gadd, 2004a, 2007a.)

genera present today were found (Taylor and Osborn, 1996; Taylor et al., 1994, 1997, 2005; Heckman et al., 2001; Butterfield, 2005). Since that time fungi have been ubiquitous components of the microbial communities of any terrestrial environment (Hawksworth, 2001), including such hostile locations as the arctic and Antarctic, hot deserts, and metal-rich and hypersaline soils (Burford et al., 2003a). One of the most successful mechanisms that enables fungi to survive in extreme subaerial environments is by the formation of mutualistic symbioses with algae and/or cyanobacteria as lichens, where the phototrophs provide a source of carbon and are protected to some degree from light and other external factors (Gorbushina et al., 1993; Sterflinger, 2000). The majority of terrestrial fungi inhabit soil environments which are perhaps more hospitable than bare rock surfaces. Fungal communities in soil include free-living and symbiotic fungi, as well as plant and animal pathogens, and unicellular yeasts.

Fungi encounter metals as components of the natural environment as well as those introduced or redistributed by human activities. Like other organisms, fungi possess a variety of properties that can influence interactions with metals, while “normal” growth and metabolism is dependent on metal and metal–mineral interactions to satisfy essential metal and associated nutrient requirements (Gadd and Griffiths, 1978). At potentially toxic metal concentrations, a variety of resistance mechanisms may be expressed: sensitive organisms may be vulnerable and population changes can result. Metal toxicity can be

influenced by the physicochemical attributes of the environment, while fungi possess a variety of properties that can ensure survival. It seems fungi can be isolated from any habitats polluted by toxic metals.

This article will outline important fungal roles and functions in rock, mineral, metal, and soil transformations, and will emphasize the importance of fungi as agents of geochemical change. It will also include fungal-mediated metal transformations, the role of fungi in the geochemistry of metal cycling, and the applied significance of these processes in environmental biotechnology. Such roles can all be included under the term “geomycology,” which can be simply defined as “the scientific study of the role of fungi in processes of fundamental importance to geology.” This includes past, current, and potential future fungal activities and such roles include the alteration and weathering of rocks and minerals, soil formation, the transformation and accumulation of metals, decomposition, and nutrient cycling. In this article, the decomposition of organic substances is included under the heading of “geomycology” since this process results in major geochemical cycling of elements in the biosphere, and, as carbon and energy sources, the metabolism of organic compounds underpins all fungal activities and interactions with environmental components. “Geomycology” can be considered to be a subset of “geomicrobiology,” namely the role of microorganisms and microbial processes in geological and geochemical processes, and is itself a subset of “microbiology,” the scientific study of microorganisms. “Geomycology” can also be considered to be a subset of “mycology” which is the scientific study of fungi. Such definitions are clearly imprecise and important topics dealt with under “geomycology” and “geomicrobiology” headings are also relevant to and also important to such research areas as geochemistry, mineralogy, hydrometallurgy, and biogeochemistry, for example. Some geomycological activity involves enzymatic oxidation or reduction of inorganic substances, although prokaryotes are more usually associated with such reactions, and these may contribute to mineral formation, transformation, and degradation. Other activities involve the biosynthesis of inorganic and organic compounds and metabolites, and the degradation of natural and anthropogenically produced carbon compounds in which both prokaryotes and eukaryotes participate. Some geomicrobial activity involves reactions where inorganic or organic products of metabolism serve as chemical reagents in reactions such as metal precipitation, metal solubilization, and mineral weathering and dissolution. Some geomicrobial activity depends on physical effects exerted on the environment by growing microorganisms which can depend on growth form and metabolism, e.g., biomechanical pressure exerted by growing fungi in rock fissures, and pH reduction due to acid excretion. Some processes may be the result of a combination of several of these general activities. While the majority of processes discussed pertain to the terrestrial environment, it should be noted that the same processes may also occur in aquatic

environments and sediments, though their significance may be different as well as influenced strongly by spatial and environmental factors. It should also be noted that detailed discussion of fungal roles and the mechanisms involved in the cycling and transformations of elements like N, P, and S is precluded here because of space limitations.

Organic matter degradation and biogeochemical cycling

The ability of fungi to utilize a wide spectrum of organic compounds is well-known. These range from simple compounds such as sugars, organic acids, and amino acids to more complex molecules which are broken down by extracellular enzymes before cellular entry. These latter compounds include natural substances like cellulose, pectin, lignin, lignocellulose, chitin and starch, but also anthropogenic products such as hydrocarbons, pesticides, and other xenobiotics. Utilization of these substances results in redistribution of component elements, primarily C, H, and O, but also N, P, S, and others (see later).

Some fungi have remarkable degradative properties, and lignin-degrading white rot fungi like *Phanerochaete chrysosporium* can degrade aromatic hydrocarbons, chlorinated organics, polychlorinated biphenyls, nitrogen-containing aromatics, and many other pesticides, dyes, and xenobiotics. Such activities are relevant to bioremediation where ligninolytic fungi have been used to treat soil contaminated with, e.g., pentachlorophenol (PCP) and polycyclic aromatic hydrocarbons (PAHs), the latter being constituents of creosote. Treatment generally involves inoculation of contaminated soil, nutrient addition, irrigation and aeration, and maintenance by land-farming procedures (Singleton, 2001). Xenobiotic-transforming fungi may need additional utilizable carbon sources because they cannot utilize these complex substrates. Inexpensive utilizable lignocellulosic wastes, such as corn cobs, straw, and sawdust are therefore supplied as nutrients. Wood-rotting and other fungi are also receiving attention for the bleaching of dyes and industrial effluents, and the biotreatment of agricultural wastes, such as forestry, pulp and paper by-products, sugarcane bagasse, coffee pulp, sugar beet pulp, apple and tomato pulp, and cyanide.

Polycyclic aromatic hydrocarbons (PAHs) enter the environment via fossil-fuel combustion, vehicle exhaust emissions, gas and coal tar manufacture, wood-preservation processes, and waste incineration (Harvey, 1997; Cerniglia and Sutherland, 2001, 2006). Aerobic biodegradation of PAHs by soil microorganisms depends on monooxygenase, peroxidase, and dioxygenase pathways; the first and third of these pathways are employed by bacteria while the first and second are found in fungi. Many fungi can metabolize PAHs but since fungi cannot generally use PAHs as their sole carbon and energy source, they must be supplemented with other carbon sources to allow co-metabolism (Cerniglia and Sutherland, 2001, 2006; Sutherland, 2004).

The transformation of PAHs by ligninolytic wood-decaying fungi involves several enzymes. Those produced by white-rot fungi include lignin peroxidase, manganese peroxidase, laccase, cytochrome P450, and epoxide hydrolase. Ligninolytic fungi metabolize PAHs via reactions involving reactive oxygen species to phenols and quinones and these may be further degraded by ring-fission enzymes. Several wood-decaying fungi (e.g., *Bjerkandera*, *Coriolopsis*, *Irpex*, *Phanerochaete*, *Pleurotus*, and *Trametes* spp.), have been investigated for bioremediation of PAH-contaminated soils. Non-ligninolytic fungi, including *Cunninghamella*, *Mucor*, *Fusarium*, and *Penicillium* spp., have also been considered for PAH bioremediation. Complete biodegradation may require the presence of mixed bacterial and fungal communities.

Fungi are also important in the degradation of naturally occurring complex molecules in the soil, an environment where the filamentous hyphal mode of growth provides several advantages, and also in aquatic habitats. Since 95% of plant tissue is composed of carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulphur, the decomposition activities of fungi are important in redistribution of these elements between organisms and environmental compartments (Table 2). As well as C, H, O, N, P, and S, another 15 elements are typically found in living plant tissues – K, Ca, Mg, B, Cl, Fe, Mn, Zn, Cu, Mo, Ni, Co, Se, Na, Si. However, all 90 or so naturally occurring elements may be found in plants, mostly at low concentrations, although this may be highly dependent on environmental conditions. These include Au, As, Hg, Pb, and U, and there are some plants that accumulate relatively high concentrations of metals Ni and Cd. Animals likewise contain a spectrum of elements in varying amounts. For example, the human body is mostly water, and 99% of the mass comprises oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus. However, many other elements are present in lower amounts including those in substances taken up as contaminants in food, air, and water. A similar situation occurs throughout the plant, animal, and microbial worlds. Therefore, any decomposition, degradative and pathogenic activities of fungi are linked to the cycling of all these constituent elements, some of which may be radionuclides accumulated from environmental sources (Table 2). This simple perspective on organic matter decomposition illustrates the global significance of fungi in geochemical element cycling and their involvement in almost all elemental cycles. Space considerations preclude detailed discussion of the mechanisms involved in fungal transformations and cycling of elements like N, P, and S and their compounds.

Organometals (compounds with at least one metal-carbon bond) can be attacked by fungi. Degradation of organometallic (and organometalloid) compounds, which are still widely used in agriculture and industry, can be carried out by fungi, either by direct biotic action (enzymes), or by the fungi facilitating abiotic degradation, for instance by alteration of pH and excretion of metabolites

Geomycology, Table 2 Fungal roles in key biogeochemical cycles of the elements. Some of the major or representative roles of fungi in elemental cycles are indicated without reference to their global significance. Major elemental movements relate to decomposition activities reliant on metabolism and the hyphal mode of growth. Note that only representative elements are shown here: virtually all elements in the Periodic Table (including actinides, lanthanides, and radionuclides) can be accumulated within or associated with fungal biomass depending on the environment. Fungi possess transport systems for essential metals; inessential metal species can also be taken up. Fungi are also capable of mediating metal bioprecipitation by, e.g., metabolite production, changing the physicochemical microenvironmental conditions around the biomass, and indirect release of metal-precipitating substances from other activities, e.g., phosphate. Fungal walls and exopolymers can sorb, bind, or entrap many substances. Redox transformations are also widespread in fungal metabolism. While most roles occur in the terrestrial aerobic environment, similar transformations may occur in aquatic environments and in sediments where fungal populations occur

Element(s)	Fungal roles in elemental cycles
C	Decomposition of organic substances; respiration (CO ₂ production); synthesis of polymers, organic metabolites, etc.; humus formation; CN ⁻ production; carbonate formation; oxalate formation; oxalate-carbonate cycle; dissolution of carbonates
H, O	Uptake, assimilation, degradation, and metabolism of organic and inorganic compounds; water uptake, transport, translocation, and conduction; respiration (CO ₂); organic and inorganic metabolite excretion
N	Decomposition of nitrogenous compounds; assimilation and transformations of organic and inorganic N compounds; fungal nitrification and denitrification; biosynthesis of N-containing biopolymers, e.g., chitin; production of N-containing metabolites and gases, e.g., N ₂ O; ammonia fermentation under anaerobic conditions; mycorrhizal N transfer to plants
P	Dissolution of inorganic phosphates and P-containing minerals in soils and rocks; decomposition of organic P-containing organic compounds; formation of insoluble P, e.g., polyphosphate, secondary phosphate minerals; release of organically bound P by phosphatases; assimilation and transformation of inorganic P species; oxidation of reduced forms of phosphate, e.g., phosphate; transformations of soil organic P; production of diphosphates and phosphonates; mycorrhizal P transfer to plants
S	Degradation of organic S-containing compounds; organic-inorganic S transformations; uptake and assimilation of organic and inorganic S compounds; SO ₄ ²⁻ reduction and assimilation; oxidation of reduced S compounds, e.g., S(0), thiosulfate, tetrathionate; sulfide production; oxidation of H ₂ S to S(0); reduction of S(0) to H ₂ S; dissolution of S-containing minerals in soils and rocks, e.g., sulfides, sulfates
Fe	Bioweathering of iron-containing minerals in rocks and soils; iron solubilization by siderophores, organic acids, metabolites, etc.; Fe(III) reduction to Fe(II)
Mn	Mn(II) oxidation and immobilization as Mn oxides; Mn(IV) reduction; indirect Mn(IV)O ₂ reduction by metabolites, e.g., oxalate; bioaccumulation of Mn oxides to surfaces, exopolymers; contribution to desert varnish formation; biosorption; accumulation; intracellular precipitation
Cr	Cr(VI) reduction to Cr(III); accumulation of Cr oxyanions
Mg, Ca, Co, Ni, Zn, Cd, Sr	Bioweathering of minerals in rocks and soil; biosorption; uptake and accumulation; bioprecipitation, e.g., oxalates, sulfides, phosphates, carbonate
Ag	Reduction of Ag(I) to Ag(0); biosorption; accumulation
K, Na, Cs	Uptake and accumulation; translocation through mycelium; concentration in fruit bodies; mobilization from minerals in soil
Cu	Mobilization from Cu-containing minerals in rocks and soils; CuS formation; biosorption; uptake and accumulation; bioprecipitation, e.g., oxalates
Se	Reductive transformation of Se oxyanions, e.g., Se(VI) to Se(IV) to Se(0); Biomethylation of Se compounds; assimilation of organic and inorganic Se compounds
Te	Reductive transformation of Te oxyanions, e.g., Te(VI) to Te(IV) to Te(0); Biomethylation of Te compounds; assimilation of organic and inorganic Te compounds
Pb	Biosorption; lead oxalate formation
Cl, Br, I	Methylation
Sn	Organotin degradation; sorption and accumulation of soluble Sn species
Au	Reduction of soluble Au species to Au(0)
As	Methylation of arsenic species, e.g., arsenite to trimethylarsine; reduction of As oxyanions, e.g., arsenate to arsenite; oxidation of As oxyanions, e.g., arsenite to arsenate
Hg	Hg methylation; reduction of Hg(II) to Hg(0); Hg volatilization as Hg(0); degradation of organomercurials; biosorption; accumulation
Al	Al mobilization from Al-containing minerals in soils and rocks; aluminosilicate dissolution; Al precipitation as oxides (early stage of bauxitization); biosorption
Si	Uptake of soluble Si species; organic Si complex formation from inorganic silicates; organic siloxane formation; silica, silicate, and aluminosilicate degradation; Si mobilization through production of chelators, acids, bases, exopolymers
U, Th	Biosorption; deposition of hydrolysis products; intracellular precipitation

(Gadd, 1993b). Organotin compounds, such as tributyltin oxide and tributyltin naphthenate, may be degraded to mono- and dibutyltins by fungal action, inorganic Sn(II) being the ultimate product (Gadd, 2000a). Organomercury compounds may be detoxified by fungal organomercury lyase, the resultant Hg(II) being subsequently reduced to less toxic, diffusible, and volatile Hg(0) by mercuric reductase (Gadd, 1993b). Degradation of persistent carbon sources, such as charcoal and black shale, can be accelerated by fungal activity, which in turn may accelerate the release of toxic metals as organic metal complexes (Wengel et al., 2006).

Transformations of rocks and minerals

Minerals are naturally occurring inorganic solids of definite chemical composition with an ordered internal structure; rocks can be considered to be any solid mass of mineral or mineral-like material. Silicates are the most common minerals with non-silicates constituting <10% of the Earth's crust, the most common being carbonates, oxides, sulfides, and phosphates. Rocks and minerals are a vast reservoir of elements, many essential for life, and such elements must be released in forms that may be assimilated by the biota. These include essential metals as well as nutrient elements like S and P (Gadd, 2007a; Gadd et al., 2005, 2007).

Microbial processes influenced by minerals

Many important microbial processes can be influenced by minerals including energy generation, nutrient acquisition, cell adhesion, and biofilm formation (Hochella, 2002), and such effects are also likely to be found within fungal populations. Essential nutrients may be acquired from mineral surfaces and this concentrates these substances above surrounding environmental levels (e.g., C, N, P, Fe, essential metals, various organic compounds) (Vaughan et al., 2002). Environmental contaminants may also be sorbed to mineral surfaces and these can be displaced by microbial activity (Kraemer et al., 1999). Potentially toxic metals released from minerals as a result of physicochemical and biological processes, may also affect microbial communities (Gadd, 2005). Such properties of mineral surfaces as microtopography, surface composition, surface charge and hydrophobicity play an important role in microbial attachment and detachment, and are therefore critical for colonization and biofilm formation, and the ecology of microbial populations, including fungi, associated with mineral substrates.

Bioweathering by fungi

Bioweathering can be defined as the erosion, decay, and decomposition of rocks and minerals mediated by living organisms. Fungi are well-suited as biological weathering agents since they can be highly resistant to extreme environmental conditions such as metal toxicity, UV radiation, and desiccation; they can adopt a variety of growth, metabolic, and morphological strategies; they can exude protons and metal-complexing metabolites, and form

mutualistic associations with animals, plants, algae, and cyanobacteria (Sterflinger, 2000; Burford et al., 2003a, b; Gadd, 2007a). Most fungi exhibit a filamentous growth habit, while some are polymorphic occurring as filamentous mycelium and unicellular yeasts or yeast-like cells, e.g., black microcolonial rock-dwelling fungi (Gorbushina, 2007). The ability of fungi to translocate water, nutrients, and organelles within the mycelial network is another important feature for exploiting heterogeneous environments (Boswell et al., 2002, 2003, 2006).

Rock surfaces may be an inhospitable habitat due to moisture deficit and nutrient limitation although many fungi can tolerate extremes in such factors as light, salinity, pH, and water potential (Gorbushina et al., 1993; Sterflinger, 2000; Verrecchia, 2000; Burford et al., 2003a, b). Many fungi can scavenge nutrients from the atmosphere and rainwater. In the subaerial rock environment, fungi can also use organic and inorganic residues on surfaces or within cracks and fissures, waste products of other microorganisms, decaying plants and insects, dust particles, aerosols, and animal feces as nutrient sources (Sterflinger, 2000). Fungi may receive protection from the presence of melanin pigments and mycosporines in their cell walls, and by the production of mucilaginous exopolymeric slime that may entrap clay particles providing extra protection (Gadd, 1993a; Gorbushina, 2007). Fungi appear to be ubiquitous components of the microbiota of all rocks, building stone, and concrete, and have been reported from a wide range of rock types, e.g., limestone, marble, granite, sandstone, basalt, gneiss, dolerite and quartz, even from the most extreme environments (Burford et al., 2003a, b; Gorbushina, 2007).

Elements found in soil largely reflect the composition of the Earth's crust, though some modification occurs by weathering, biogenic and anthropogenic activities: chemical changes include mineral dissolution while biological activity causes enrichment of C, N, and S. Elements and minerals that remain can reform as secondary minerals. In soil, fungus–mineral interactions are an integral component of environmental cycling (Figure 2). Mycorrhizal fungi are particularly important in mineral weathering and dissolution of insoluble metal compounds. Fungi are also important components of lithobiotic biofilm communities at mineral–microbe interfaces where they interact with the substrate both geophysically and geochemically: this can result in the formation of patinas, films, varnishes, crusts, and stromatolites (Gadd, 2007a; Gorbushina, 2007).

Biomechanical deterioration of rocks can occur through hyphal penetration and burrowing into decaying material and along crystal planes in, e.g., calcitic and dolomitic rocks (Sterflinger, 2000; Gadd, 2007a). Cleavage penetration can also occur with lichens (Banfield et al., 1999). Spatial exploration of the environment to locate and exploit new substrates is facilitated by a range of sensory responses that determine the direction of hyphal growth. For example, thigmotropism (or contact guidance) is a well-known property of fungi that grow on and within solid substrates with the direction of fungal growth being influenced by grooves,

Geomycology, Figure 2 Indicated role of fungi (as well as other biota) in soil solution reactions relevant to metal(loid) speciation and partitioning between solid, liquid, and gaseous phases (derived from Cotter-Howells and Paterson, 2000). The soil solution has a pivotal role in most reactions of metabolic and geochemical significance in the soil. The arrows linking the outer components of the diagram that represent the fungi, soil atmosphere, and solid phase indicate those direct reactions that may occur with little or no significant involvement of the soil solution. These could include utilization or production of gases (e.g., O_2 and CO_2 respectively), direct attack of solid phases, and adsorption of gases onto solid phase surfaces. However, in the absence of water, these reactions may be limited, especially those dependent on metabolism.

ridges, and pores (Bowen et al., 2007a, b). However, biochemical actions are believed to be more important processes than mechanical degradation. Biochemical weathering of rocks and minerals can occur through excretion of, e.g., H^+ , organic acids and other metabolites. This can result in changes in the mineral microtopography through pitting and etching of surfaces to complete dissolution of mineral grains (Ehrlich, 1998; Gharieb et al., 1998; Kumar and Kumar, 1999; Adeyemi and Gadd, 2005). Fungi generally acidify their microenvironment via a number of mechanisms, which include the excretion of protons and organic acids, while respiratory CO_2 can result in carbonic acid formation. In addition, fungi excrete a variety of other metal-complexing metabolites (e.g., siderophores, carboxylic acids, amino acids, and phenolic compounds) (Burgstaller and Schinner, 1993). The weathering of sandstone monuments by fungi has been attributed to the production of, e.g., acetic, oxalic, citric, formic, fumaric, glyoxylic, gluconic, succinic, and tartaric acids.

Concrete biodeterioration in radioactive waste disposal

Cement and concrete are used as barriers in all kinds of nuclear waste repositories. Despite the theoretical service

life of concrete reaching up to one million years, biocorrosion is an important factor to take into account. All types of building and ceramic materials, concrete, and cement can be deteriorated by microorganisms and in some environments, fungi dominate the microbiota and play an important role in biodeterioration of concrete (Gu et al., 1998; Nica et al., 2000; Zhdanova et al., 2000). Fungal attack on concrete can be strongly and mildly aggressive caused by protons and organic acids and production of hydrophilic slimes leading to biochemical and biophysical/biomechanical deterioration (Fomina et al., 2007a). Fungal degradation may proceed more rapidly than bacterial degradation with complexolysis suggested as the main mechanism of calcium mobilization. Microfungi from the genera *Aspergillus*, *Alternaria*, and *Cladosporium* were able to colonize samples of the concrete used as the radioactive waste barrier in the Chernobyl reactor and leached iron, aluminium, silicon, and calcium, and re-precipitated silicon and calcium oxalate in their microenvironment (Fomina et al., 2007a). Fungi are also important members of the microbial communities (including lichens) that colonize and deteriorate “normal” concrete and cement used in buildings and other structures.

Geomycology, Table 3 Some examples of biomineralization of fungal hyphae and lichen thalli with secondary minerals. The hydration state of some minerals is unclear and only stated when this is specifically identified. The list is not exhaustive and many other mycogenic minerals are possible, as well as many other fungal species capable of mediating their formation (taken from Gadd, 2007a; Burford et al., 2003a, b, and also adapted from a number of sources including Grote and Krumbein, 1992; de la Torre and Gomez-Alarcon, 1994; Easton, 1997; Verrecchia, 2000; Haas and Purvis, 2006; Burford et al., 2006)

Mineral	Fungal hyphae	Lichen thalli	Organism(s)
Birnessite ((Na, Ca, K) Mn ₇ O ₁₄ ·3H ₂ O)	Fungi on siderite boulder and Natraqualf soil		<i>Alternaria</i> spp. <i>Cladosporium</i> spp.
Cadmium oxalate (CdC ₂ O ₄)	Fungi cultured with, e.g., cadmium phosphate, or other cadmium compounds and minerals		<i>Beauveria caledonica</i>
Calcite (CaCO ₃)	Fungi on stalactites, Quaternary eolianites and calcretes; fungi grown in limestone cement microcosms and laboratory media containing insoluble calcium compounds, e.g., calcite, or other Ca-containing compounds and minerals	Lichens on roofing tiles, andesite, volcaniclastite and exposed caliche plates in weathered basaltic and rhyolitic rocks	<i>Caloplaca aurantia</i> <i>Doratomyces</i> sp. <i>Penicillium coryphilum</i> <i>Penicillium simplicissimum</i> <i>Verrucaria</i> spp.
Cobalt oxalate (CoC ₂ O ₄)	Fungi cultured with Co compounds		<i>Aspergillus niger</i>
Desert Varnish (MnO and FeO)	Fungal action on siderite and rhodochrosite in desert regions and sandstone limestone and granite monuments		<i>Alternaria alternata</i> <i>Cladosporium cladosporoides</i> <i>Lichenothelia</i> spp. <i>Penicillium frequentans</i> <i>Penicillium steckii</i> <i>Phoma glomerata</i>
Ferrihydrite (Fe ₂ HO ₈ ·H ₂ O or 5Fe ₂ O ₃ ·9H ₂ O)		Lichen on recent lava flow, on olivine of basalt, gabbro and augite	<i>Pertusaria corallina</i> <i>Stereocaulon vulcani</i>
Glushinskite (MgC ₂ O ₄ ·2H ₂ O)	Fungi cultured with hydromagnesite	<i>Lichen/rock interface on serpentinite</i>	<i>Lecanora atra</i> <i>Penicillium simplicissimum</i>
Goethite (FeO(OH))		Lichen on metamorphic rocks, feldspars, granite, and gneiss	<i>Parmelia conspersa</i> <i>Parmelia tiliacea</i>
Halloysite (Al ₂ Si ₂ O ₅ (OH) ₄ ·2H ₂ O)		Action of lichens on cave deposits and waters	<i>Lasallia</i> spp. <i>Mucor</i> spp. <i>Parmelia</i> spp. <i>Penicillium</i> spp. <i>Rhizocarpon</i> spp. <i>Rhizopus</i> spp.
Humboldtine (FeC ₂ O ₄ ·2H ₂ O)		Lichens on Fe rich crystalline limestone and cupriferous rocks	<i>Acarospora smargdula</i> <i>Aspicila alpina</i> <i>Lecidea lactea</i>
Hydrocerussite (Pb ₃ (CO ₃) ₂ (OH) ₂)		Mycobiont of lichen in ruins of a lead-smelting mill	<i>Stereocaulon vesuvianum</i>
Hydromagnesite (Mg ₅ (CO ₃) ₄ (OH) _{2.4} ·H ₂ O)	Fungi cultured with hydromagnesite		<i>Penicillium simplicissimum</i>
Lead oxalate, lead oxalate dehydrate (PbC ₂ O ₄ , PbC ₂ O ₄ ·2H ₂ O)	Fungi cultured with pyromorphite, or in laboratory media containing Pb compounds		<i>Aspergillus niger</i> <i>Beauveria caledonica</i>
Mn-oxalate (MnC ₂ O ₄ ·2H ₂ O)	Fungi cultured in laboratory media containing Mn compounds	Lichen on Mn ore	<i>Aspergillus niger</i> <i>Pertusaria corallina</i>
Montmorillonite (X _{0.33} Al ₂ Si ₂ O ₁₀ (OH) ₂ ·nH ₂ O) [X = Na ⁺ , K ⁺ , Ca ²⁺ , Mg ²⁺]		Action of lichens on cave deposits and waters	<i>Lasallia</i> spp. <i>Mucor</i> spp. <i>Parmelia</i> spp. <i>Penicillium</i> spp. <i>Rhizocarpon</i> spp. <i>Rhizopus</i> spp.
Moolooite (CuC ₂ O ₄ ·nH ₂ O (n < 1))	Fungi cultured with, e.g., copper phosphate, or other Cu-containing compounds and minerals	Lichens on cupriferous rocks	<i>Acarospora rugulosa</i> <i>Aspergillus niger</i> <i>Beauveria caledonica</i> <i>Lecidea inops</i> <i>Lecidea lactea</i> <i>Rhizopogon rubescens</i> <i>Serpula himantioides</i>

Geomycology, Table 3 (Continued)

Mineral	Fungal hyphae	Lichen thalli	Organism(s)
Strontium oxalate hydrate ($\text{SrC}_2\text{O}_4 \cdot \text{H}_2\text{O}$; $\text{SrC}_2\text{O}_4 \cdot 2.5\text{H}_2\text{O}$)	Fungi cultured with strontianite (SrCO_3), or other Sr-containing compounds and minerals		<i>Penicillium simplicissimum</i> <i>Pseudallescheria boydii</i> <i>Serpula himantoides</i>
Todorokite ((Mn, Ca, Mg) $\text{Mn}_3\text{O}_7 \cdot \text{H}_2\text{O}$)	Fungi in cave deposits and waters		<i>Mucor</i> spp. <i>Penicillium</i> spp. <i>Rhizopus</i> spp.
Uramphite ($\text{NH}_4(\text{UO}_2)$ (PO_4) $\cdot 3\text{H}_2\text{O}$) and Chernikovite ($(\text{H}_3\text{O})_2(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$)	Fungi cultured with uranium oxides, metallic depleted uranium, or other U- containing compounds and minerals		<i>Beauveria caledonica</i> <i>Hymenoscyphus ericae</i> <i>Rhizopogon rubescens</i> <i>Serpula himantoides</i>
Weddellite ($\text{CaC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$)	In leaf litter and soils; fungi grown on limestone cement microcosms, and laboratory media containing insoluble calcium compounds, e.g., calcite, or other Ca-containing compounds and minerals	On serpentinite, cupriferous rocks, andesite and volcaniclastite	<i>Acarospora rugulosa</i> <i>Aphylllophorales</i> spp. <i>Aspicilia calcarea</i> <i>Caloplaca aurantia</i> <i>Caloplaca flavescens</i> <i>Gastrum</i> spp. <i>Hypogymnia physodes</i> <i>Hysterangium crassum</i> <i>Lecanora atra</i> <i>Lecanora rupicola</i> <i>Lecidea inops</i> <i>Lecidea lactea</i> <i>Ochrolechia parella</i> <i>Penicillium coryliphilum</i> <i>Penicillium simplicissimum</i> <i>Pseudallescheria boydii</i> <i>Serpula</i> <i>himantoides</i>
Whewellite ($\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$)	In Nari limecrusts, Quaternary calcretes, forest leaf litter and soils; fungi grown on limestone cement microcosms, and laboratory media containing insoluble calcium compounds, e.g., calcite, or other Ca-containing compounds and minerals	On basalt, serpentinite, cupriferous rocks, gabbro, dolerite, andesite and volcaniclastite	<i>Acarospora rugulosa</i> <i>Acarospora smargdula</i> <i>Aspicilia alpina</i> <i>Aspicilia calcarea</i> <i>Aspicilia radiosa</i> <i>Caloplaca flavescens</i> <i>Doratomyces</i> sp. <i>Hypogymnia physodes</i> <i>Lecanora atra</i> <i>Lecanora rupicola</i> <i>Lecidea inops</i> <i>Lecidea lactea</i> <i>Ochrolechia parella</i> <i>Parmelia conspersa</i> <i>Parmelia subrudecta</i> <i>Penicillium coryliphilum</i> <i>Penicillium simplicissimum</i> <i>Pertusaria corallina</i> <i>Pseudallescheria boydii</i> <i>Serpula</i> <i>himantoides</i> <i>Xanthoria ectaneoides</i> <i>Aspergillus niger</i> <i>Beauveria caledonica</i> <i>Rhizopogon rubescens</i> <i>Suillus collimitus</i>
Zinc oxalate ($\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$)	Fungi exposed to, e.g., zinc oxide, zinc phosphate		

Formation of secondary mycogenic minerals

Formation of secondary minerals by fungi can occur through metabolism-independent and -dependent processes (Gadd, 2007a) (Table 3). Precipitation, nucleation, and deposition of crystalline material on and within cell walls are influenced by factors such as pH and wall

composition. This process may be important in soil as the precipitation of carbonates, phosphates, and hydroxides increases soil aggregation. Cationic species of Si(IV), Fe(III), Al(III), and Ca(II) that may be released through dissolution mechanisms, stimulate precipitation of compounds that may bond soil particles. Hyphae and any

associated exopolymeric material can also enmesh soil particles, and also release organic metabolites that enhance aggregate stability (Bronick and Lal, 2005).

Carbonates

Microbial carbonate precipitation coupled with silicate weathering could provide an important sink for CO_2 in terrestrial environments. In limestone, fungi and lichens are considered to be important agents of mineral deterioration. In contrast, many near-surface limestones (calcretes), calcic, and petrocalcic horizons in soils are secondarily cemented with calcite (CaCO_3) and whewellite (calcium oxalate monohydrate, $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$). The presence of fungal filaments mineralized with calcite (CaCO_3), together with whewellite (calcium oxalate monohydrate, $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$), has been reported in limestone and calcareous soils from a range of localities (Verrecchia, 2000). Calcium oxalate can also be degraded to calcium carbonate, and this may again cement preexisting limestones (Verrecchia et al., 2006). During the decomposition of fungal hyphae, calcite crystals can act as sites of further secondary calcite precipitation. Calcite will also readily nucleate on chitin, the major component of fungal cell walls. Other experimental work has demonstrated fungal precipitation of secondary calcite, whewellite, and glushkinskite ($\text{MgC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$) (Figure 3) (Burford et al., 2003b, 2006; Gadd, 2007a).

Oxalates

Many fungi can produce metal oxalates by interaction with a variety of different metals and metal-bearing minerals (Ca, Cd, Co, Cu, Mg, Mn, Sr, Zn, Ni, and Pb) (Figure 4) (Sayer and Gadd, 1997; Gadd, 2007a) (Table 3). Calcium oxalate dihydrate (weddelite) and the more stable calcium oxalate monohydrate (whewellite) are the most common forms of oxalate associated with fungi: biotic fungal calcium oxalate can exhibit a variety

of crystalline forms (tetragonal, bipyramidal, plate-like, rhombohedral or needles) (Arnott, 1995). Precipitation of calcium oxalate can act as a reservoir for calcium and also influences phosphate availability. The formation of toxic metal oxalates may also provide a mechanism enabling fungi to tolerate high concentrations of toxic metals (Gadd, 1993a; Jarosz-Wilkolazka and Gadd, 2003).

Reductive and oxidative precipitation

Reduced forms of metals and metalloids (e.g., elemental silver, gold, selenium, tellurium) can be precipitated by many fungi (Kierans et al., 1991; Gharieb et al., 1995, 1999; Gadd, 1993b). The reductive ability of fungi is manifest by black coloration of fungal colonies precipitating elemental Ag or Te, or a red coloration for those precipitating elemental Se. An oxidized metal layer (patina) a few millimetres thick found on rocks and in soils of arid and semi-arid regions, called desert varnish, is also believed to be of microbial origin with some proposed fungal involvement. Fungi can oxidize Mn(II) and Fe(II) in metal-bearing minerals such as siderite (FeCO_3) and rhodochrosite (MnCO_3) and precipitate them as oxides (Grote and Krumbein, 1992).

Other mycogenic minerals

Combinations of biotic and abiotic factors can lead to deposition of a variety of other secondary minerals associated with fungal biomass, e.g., birnessite, MnO and FeO, ferrihydrite, iron gluconate, calcium formate, forsterite, goethite, halloysite, hydrocerussite, todorokite, moolooite, montmorillonite, and uranium phosphates (Figure 5) (Gadd, 2007a) (Table 3). Such biomineralization immobilizes metals and therefore limits metal bioavailability.

Geomycology, Figure 3 Glushkinskite ($\text{MgC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$) and hydromagnesite ($\text{Mg}_5(\text{CO}_3)_4(\text{OH})_2 \cdot 4\text{H}_2\text{O}$) deposition around hyphae of *Penicillium simplicissimum* cultured on media containing hydromagnesite. (Burford E. P., and Gadd G. M., 2004 unpublished data.)

Geomycology, Figure 4 Moolooite (copper oxalate, $\text{CuC}_2\text{O}_4 \cdot n\text{H}_2\text{O}$ ($n < 1$)) formation around hyphae of *Beauveria caledonica* grown on media containing copper phosphate. The moolooite has been fractured showing the extensive precipitation around hyphae, and the resulting holes or tunnels. (Fomina M., and Gadd G. M., 2005 unpublished data; see also Fomina et al., 2005a.)

Geomycology, Figure 5 Extensive precipitation of uranium phosphate minerals, uramphite ($\text{NH}_4(\text{UO}_2)(\text{PO}_4) \cdot 3\text{H}_2\text{O}$) and chernikovite ($(\text{H}_3\text{O})_2(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$) around hyphae of *Beauveria caledonica* cultured on media containing uranium oxide (U_3O_8). (Fomina M., et al., 2007 unpublished data; see also Fomina et al., 2007b.)

Fungal–clay interactions

Clay mineral formation and impact on soil properties

Silicon dioxide, when combined with oxides of Mg, Al, Ca, and Fe, forms the silicate minerals in rocks and soil. Silicates are the largest class of minerals comprising 30% of all minerals and making up 90% of the Earth's crust (Ehrlich, 2002). These minerals are unstable in the biosphere and break down to form clays. Microorganisms, including fungi, play a fundamental role in the dissolution of silicates in rock weathering, and therefore in the formation of clay minerals, and soil and sediment formation (Banfield et al., 1999). The presence of clay minerals can be a typical symptom of biogeochemically weathered rocks, and this has been observed for symbiotic fungal associations (lichens and ectomycorrhizas) (Barker and Banfield, 1998; Arocena et al., 1999). Some studies have shown that the transformation rate of mica and chlorite to 2:1 expandable clays was predominant in the ectomycorrhizosphere compared to non-ectomycorrhizosphere soils, likely to be a result of the high production of organic acids and direct extraction of K and Mg by the fungal hyphae (Arocena et al., 1999).

Soil can be considered to be a biologically active loose mass of weathered rock fragments mixed with organic matter, and is the ultimate product of rock weathering, i.e., interactions between the biota, climate, and rocks. Clay minerals are generally present in soil in larger amounts than organic matter and because of their adsorptive and ion-exchange capacity, they perform a significant buffering function in mineral soils and are important reservoirs of cations and organic molecules.

Biological effects of clay minerals

Fungi are generally in close proximity to clay minerals in soils and sediments. Several studies have shown that interactions of microorganisms with solid adsorbents lead to an increase in biomass, growth rate, and production of

various enzymes and metabolites. Stimulatory effects may arise from the abilities of different clays to serve as pH buffers, as a source of metal cationic nutrients, as specific adsorbents of metabolic inhibitors, other nutrients and growth stimulators; and modifiers of the microbial microenvironment because of their adsorptive capacity. However, some clays may inhibit fungal growth and metabolism (Stotzky, 1966).

Fungal–clay mineral interactions in soil aggregation

Fungal–clay mineral interactions play an important role in soil development, aggregation and stabilization (Burford et al., 2003a). Fungi entangle soil particles in their hyphae forming stable microaggregates and also take part in exopolysaccharide-mediated aggregation. Interactions between hyphae and solid particles are subject to complex forces of both a physicochemical (electrostatic, ionic, hydrophobic effects, etc.) and biological nature (chemotropism, production of specific enzymes, polysaccharides, lectins and other adhesins, etc.) (Ritz and Young, 2004). Interactions between clay minerals and fungi alter the adsorptive properties of both clays and hyphae (Morley and Gadd, 1995; Fomina and Gadd, 2002).

Clay and silicate weathering by fungi

Fungi and bacteria play an important role in the mobilization of silica and silicates. Their action is mainly indirect, either through the production of chelates or the production of acids, mineral or organic (including oxalic), or, as for certain bacteria, the production of ammonia or amines (Ehrlich, 2002).

Metal, metalloid, radionuclide, and organometal transformations

Metals and their compounds interact with fungi in various ways depending on the metal species, organism, and environment, while fungal metabolism also influences metal speciation and mobility (Gadd and Griffiths, 1978; Gadd, 1992, 1993a, 2004a, b, 2005, 2007a). Many metals are essential for life, e.g., Na, K, Cu, Zn, Co, Ca, Mg, Mn, and Fe, but all can exert toxicity when present above certain threshold concentrations. Other metals, e.g., Cs, Al, Cd, Hg, and Pb, have no known metabolic function in fungi but all can be accumulated. Metal toxicity is affected by environmental conditions and the chemical behavior of the particular metal species. Despite potential toxicity, many fungi survive and grow in metal-rich locations and a variety of mechanisms, both active and incidental, contribute to tolerance. Fungi have many properties which influence metal mobility and toxicity including the production of metal-binding proteins, organic and inorganic precipitation, active transport, and intracellular compartmentalization, while major constituents of cell walls, e.g., chitin and melanin, have significant metal-binding abilities (Gadd, 2004a, b, 2005, 2006). Other properties lead to metal solubilization from organic and inorganic sources (Gadd, 2007a).

Fungi can also transform certain metals, metalloids (elements with properties intermediate between those of metals and non-metals, e.g., arsenic, selenium, and tellurium), organometallic compounds and metal radionuclides by, e.g., oxidation, reduction, methylation, and dealkylation (Gadd, 1993b, 2004a, b). Such transformations alter chemical speciation and may modify mobility and toxicity. For example, methylated selenium derivatives are volatile and less toxic than inorganic forms while reduction of metalloid oxyanions, such as selenite or tellurite to amorphous elemental selenium or tellurium respectively, results in immobilization and detoxification. All the mechanisms by which fungi (and other microorganisms) effect changes in metal speciation and mobility are survival determinants but also components of biogeochemical cycles for metals, and many other associated elements including carbon, nitrogen, sulfur, and phosphorus (Gadd, 2004a, 2006, 2007a, 2008). They may be simply considered in terms of metal mobilization or immobilization mechanisms.

Metal mobilization

Metal mobilization from rocks, minerals, soil, and other substrates can be achieved by protonolysis, resulting in carbonic acid formation from respiratory CO₂, complexation by excreted metabolites and Fe(III)-binding siderophores, and methylation which can result in volatilization. In addition, other excreted metabolites with metal-complexing properties, e.g., amino acids, phenolic compounds, and organic acids may also play a role. Fungal-derived carboxylic acids can play an important role in chemical attack of mineral surfaces and these provide protons as well as a metal-chelating anion (Burgstaller and Schinner, 1993). Oxalic acid can act as a leaching agent for those metals that form soluble oxalate complexes, including Al and Fe (Strasser et al., 1994). Solubilization mechanisms can also have consequences for mobilization of metals from toxic metal containing minerals, e.g., pyromorphite (Pb₅(PO₄)₃Cl), contaminated soil, and other solid wastes (Sayer et al., 1999; Fomina et al., 2004, 2005b, c). Fungi can also mobilize metals and attack mineral surfaces by redox processes: Fe(III) and Mn(IV) solubility is increased by reduction to Fe(II) and Mn(II) respectively. Reduction of Hg(II) to volatile elemental Hg(0) can also be mediated by fungi (Gadd, 1993b).

Removal of metals from industrial wastes and by-products, low grade ores and metal-bearing minerals by fungal “heterotrophic leaching” is relevant to metal recovery and recycling and/or bioremediation of contaminated solid wastes (Burgstaller and Schinner, 1993; Gadd, 2007a, b). Although fungi need a source of carbon and aeration, they can solubilize metals at higher pH values than thiobacilli and could perhaps become important where leaching with such bacteria is not possible and in bioreactors. Leaching of metals with fungi can be effective although a high level of organic acid production may be necessary. Other possible applications of fungal metal

solubilization are the removal of unwanted phosphates, and metal recovery from scrap electronic and computer materials (Brandl, 2001).

The ability of fungi, along with bacteria, to transform metalloids has been utilized successfully in the bioremediation of contaminated land and water. Selenium methylation results in volatilization, a process which has been used to remove selenium from the San Joaquin Valley and Kesterson Reservoir, California, using evaporation pond management and primary pond operation (Thomson-Eagle and Frankenberger, 1992).

Metal immobilization

Fungal biomass provides a metal sink, either by metal biosorption to biomass (cell walls, pigments and extracellular polysaccharides), intracellular accumulation and sequestration, or precipitation of metal compounds onto and/or around hyphae (Gadd, 1993a, 2000b, c, 2001a, b, c, 2007a; Baldrian, 2003; Fomina et al., 2007b, c). Fungi are effective biosorbents for a variety of metals including Ni, Zn, Ag, Cu, Cd, and Pb, and this can be an important passive process in both living and dead biomass (Gadd, 1990, 1993a; Sterflinger, 2000). The presence of chitin, and pigments like melanin, strongly influences the ability of fungi to act as sorbents. In a biotechnological context, fungi and their by-products have received considerable attention as biosorbent materials for metals and radionuclides (de Rome and Gadd, 1987; Gadd and White, 1989, 1990, 1992; White et al., 1995). Fungi can also precipitate several inorganic and organic compounds, e.g., oxalates, oxides, and carbonates, and this can lead to formation of biogenic minerals (mycogenic precipitates) as discussed previously (Gadd, 2007a).

Halide transformations

Fungi have the ability to produce a variety of atmospheric methyl halides. This ability is widespread in both free-living and symbiotic fungi, and is dependent on substrate concentrations and community composition (Redeker et al., 2004). The production of chloromethane (CH₃Cl) by wood-rotting fungi, e.g., *Phellinus* spp., may be particularly significant with one estimate of annual global input to the atmosphere from this source being 160,000t of which 75% is released from tropical and subtropical forests (Watling and Harper, 1998). Filamentous fungi may also contribute to the global circulation of stable iodine and also the long-lived radioiodine, ¹²⁹I (half-life: 1.6 × 10⁷ years), released from nuclear facilities into the environment (Ban-nai et al., 2006).

Fungal symbioses in mineral transformations

One of the most remarkable adaptations of fungi for exploitation of the terrestrial environment is their ability to form mutualistic partnerships with plants (mycorrhizas) and algae or cyanobacteria (lichens). Symbiotic fungi are provided with carbon by the photosynthetic partners

(photobionts), while the fungi may protect the symbiosis from harsh environmental conditions (e.g., desiccation, metal toxicity), increase the absorptive area, and provide increased access to mineral nutrients.

Lichens

Lichens are fungi that exist in facultative or obligate symbioses with one or more photosynthesizing partners, and play an important role in many biogeochemical processes. The lichen symbiosis formed between the fungal partner (mycobiont) and the photosynthesizing partner (algal or cyanobacterial photobiont) enables lichens to grow in practically all surface terrestrial environments: an estimated 6% of the Earth's land surface is covered by lichen-dominated vegetation (Haas and Purvis, 2006). Lichens are pioneer colonizers of fresh rock outcrops. Globally, lichens play an important role in the retention and distribution of nutrient (e.g., C, N) and trace elements, in soil formation, and in rock weathering. Alteration of bedrock minerals and synthesis of biominerals in the proximity of lichens gives rise to different chemical microenvironments and emphasizes their participation in mineral nutrient cycling (Banfield et al., 1999). Lichens can accumulate metals such as lead (Pb), copper (Cu), and many other elements of environmental concern, including radionuclides, to high levels. They can also form a variety of metal-organic biominerals, especially during growth on metal-rich substrates. For example, on copper-sulfide bearing rocks, precipitation of copper oxalate (moolooite) can occur within the lichen thallus (Purvis, 1996; Purvis and Halls, 1996).

Mycorrhizas

Nearly all land plants depend on symbiotic mycorrhizal fungi (Smith and Read, 1997). Two main types of mycorrhizas include endomycorrhizas where the fungus colonizes the interior of host plant root cells (e.g., ericoid and arbuscular mycorrhizas) and ectomycorrhizas where the fungus is located outside plant root cells. Mycorrhizal fungi are involved in proton-promoted and ligand-promoted metal mobilization from mineral sources, metal immobilization within biomass, and extracellular precipitation of mycogenic metal oxalates (Fomina et al., 2004, 2005b). Biogeochemical activities of mycorrhizal fungi lead to changes in the physicochemical characteristics of the root environment and enhanced weathering of soil minerals resulting in metal release. Ectomycorrhizal mycelia may respond to the presence of different soil silicate and phosphate minerals (apatite, quartz, potassium feldspar) by regulating their growth and activity, e.g., colonization, carbon allocation, and substrate acidification (Rosling et al., 2004a, b).

During growth, mycorrhizal fungi often excrete low molecular weight carboxylic acids (Martino et al., 2003; Fomina et al., 2004). The weathering of hornblendes, feldspars, and granitic bedrock in certain soils has been attributed to oxalic, citric, succinic, formic, and malic acid

excretion by ectomycorrhizal hyphae which can produce micro- to millimolar concentrations of these organic acids. Ectomycorrhizal fungi (*Suillus granulatus* and *Paxillus involutus*) can release elements from apatite and wood ash (K, Ca, Ti, Mn, Pb) and accumulate them in the mycelia (Wallander et al., 2003). Ericoid mycorrhizal and ectomycorrhizal fungi can dissolve a variety of cadmium, copper, zinc, and lead-bearing minerals including metal phosphates (Leyval and Joner, 2001; Martino et al., 2003; Fomina et al., 2004, 2005b). Mobilization of phosphorus is generally regarded as one of the most important functions of mycorrhizal fungi.

Summary

The biogeochemical importance of fungi is significant in several key areas. These include organic and inorganic transformations, nutrient and element cycling, rock and mineral transformations, bioweathering, mycogenic mineral formation, fungal-clay interactions, and metal-fungal interactions. While such transformations can occur in both aquatic and terrestrial habitats, it is in the terrestrial environment where fungi probably have the greatest influence especially when considering soil, rock, and mineral surfaces, and the plant-root-soil interface. Of special significance are the mutualistic symbioses, lichens and mycorrhizas. Geochemical transformations that take place can influence plant productivity and the mobility and speciation of toxic elements, and are therefore of considerable socioeconomic relevance. Some fungal transformations have beneficial applications in environmental biotechnology, e.g., in metal and radionuclide leaching, recovery and detoxification, and xenobiotic and organic pollutant degradation. They may also result in adverse effects when these processes are associated with the degradation of foodstuffs, natural products, and building materials, including wood, stone, and concrete.

H

HABITAT

The physical location or dwelling place of a particular organism, where an individual ecotype can be found or isolated from. See entry “*Microbial Communities, Structure, and Function*” for further reading.

HALOBACTERIA – HALOPHILES

Helga Stan-Lotter
University of Salzburg, Salzburg, Austria

Definition

Halobacteria (plural), *halobacterium* (singular). Colloquial for halophilic archaeobacteria (or archaea), which are single-celled life forms. Synonyms: Haloarchaea (plural), haloarchaeon (singular).

Halobacterium. The name of a genus of the archaeal family *Halobacteriaceae* (Grant, 2001).

Halophilic. Requires a salt-rich environment for growth and survival.

Introduction

Saline waters dominate the earth, with the oceans holding 97% of the planet's water (a total of 1.338×10^9 km³; <http://ga.water.usgs.gov/edu/earthwherewater.html>). Saline inland seas, groundwater, and saltwater lakes hold another 0.9–0.94%, which exceeds the volume of the world's available freshwater ($\sim 1.1 \times 10^7$ km³). The definition of a hypersaline environment is one that possesses a salt concentration greater than that of seawater (>3.5% w/v). Water-containing environments are usually described as thalassohaline or athalassohaline (see

Chapters “*Saline Lakes*,” “*Soda Lakes*”). Thalassohaline waters are marine-derived and therefore contain, at least initially, the seawater composition; with increasing evaporation, the concentration of various salts is changing. Athalassohaline waters may also receive influx of seawater; however, the chemical composition is mainly determined by geological, geographical, and topographical parameters.

Interactions between halophilic microorganisms and geological materials have been recognized early in the history of mankind and continue to impact human endeavors, including the exploration of energy sources, the storage of waste, the search for extraterrestrial life (see Chapter “*Deep Biosphere of Salt Deposits*”). For example, the evaporation of seawater for the purpose of making salt and the concomitant development of red color of brines, which is due to pigmented microorganisms, have been described already 2,700 years ago (Oren, 2002). It was also observed early that the presence of microorganisms in solar salterns enhances the precipitation and the yield of salt (Oren, 2002). Halite, the mineral of sodium chloride, primarily forms from the evaporation of seawater. Subsurface deposits of halite occur in many areas and are far more abundant than was previously recognized. The advent of widespread oil drilling revealed a frequent association of ancient salt deposits and the presence of the biogenic energy sources, oil and methane (Sassen et al., 1994). The potential impact of viable halophilic microorganisms in salt deposits (see Chapter “*Deep Biosphere of Salt Deposits*”), some of which are being used as storage sites for long-lived radioactive isotopes such as transuranic wastes, has been the focus of much research. The striking discovery of extraterrestrial halite in meteorites (see Chapter “*Deep Biosphere of Salt Deposits*”) and recently, in salt pools on Mars (Osterloo et al., 2008) make a search for halophilic microorganisms on other planets or moons plausible.

Saline environments and their inhabitants

Organisms occur within a range of salinities, from distilled water to saturated salt solutions, and may be loosely classified as non-, slightly, moderately, or extremely halophilic, requiring about 0.2 M, 0.2–0.85 M, 0.85–2.5 M, and 2.5–5.2 M NaCl, respectively, for growth. The largest saline environment, seawater, contains 31–38 g of total dissolved salts per liter, nearly 80% of which is NaCl. Hypersaline environments are characterized by higher salinities than seawater. The oceans are inhabited by a great diversity of organisms; when seawater is evaporating, the biological diversity decreases with increasing concentration of salt. Macroscopic organisms such as salt-tolerant fish (e.g., *Cyprinodon variegatus* and *Menidia beryllina*) are no longer found at concentrations of more than about 11% salt (1.88 M NaCl); copepods (fleas), turbellarian worms, and some rotifers tolerate 15–17% salt. Interestingly, several invertebrates such as brine shrimp (*Artemia salina*) or brine flies (*Ephydra cinerea*) are capable of survival at NaCl concentrations of 30–33% (~5 M; Javor, 1989). However, the dominating organisms in saturated brines are extremely halophilic microorganisms which grow optimally in the presence of 2.5–5.2 M NaCl and are generally unable to grow in less than 1.7 M NaCl. They can occur at such high cell densities (up to 10^8 colony forming units per milliliter) that they cause brines to turn bright red or purplish. Figure 1 shows a commercial salt-producing facility where seawater is evaporating in a series of ponds. The colors of the pools are caused by carotenoid pigments, which are contained in the membranes of haloarchaea, or by the chlorophylls of halophilic algae or cyanobacteria. Typical haloarchaea in such communities are species of the genera *Halobacterium*, *Halorubrum*, and *Halococcus*, halophilic bacteria such as *Ectothiorhodospira halochloris*, *Salinibacter ruber*, cyanobacteria (e.g., *Aphanothece halophytica*, *Phormidium* sp. and *Schizothrix arenaria*), and green algae (e.g., *Dunaliella salina* and *Asteromonas*

gracilis). Figure 2 shows two characteristic haloarchaeal morphologies – *Halobacterium salinarum* NRC-1 grows as single rod-shaped cells; *Halococcus salifodinae* cells are roundish and tend to aggregate into large clusters.

Crude solar salt contains large numbers of viable bacteria and archaea (about 10^5 – 10^6 colony forming units per milliliter; Oren, 2002). When using this salt for the preservation of fish, meat, and hides, damage in the form of red discoloration of the goods was noted under conditions of moisture and elevated temperatures. These observations started the early research on halophilic microorganisms in the 1920s–1930s. Only much later – in the 1980s – was it recognized that most halophiles from such sources belonged to the archaea. The haloarchaea are not pathogenic; in fact, some are used in traditionally fermented foods in Asia for human consumption (Oren, 2002).

There exist other hypersaline environments which are not directly derived from seawater and are called athalassohaline (see above and Chapter “Soda Lakes”); often they are remnants of prehistoric inland lakes, such as the Dead Sea and the Great Salt Lake. Additional larger lakes include Mono Lake in California, soda lakes in Egypt and China, Lake Magadi in Kenya, and Lake Eyre in Australia. The chemical composition varies depending on the geology of the surroundings, but overall salinity is usually between 200 and 340 g/l of dissolved salts. Soda lakes are an example of naturally occurring alkaline environments which may also be hypersaline, and are characterized by the presence of large amounts of sodium carbonate and correspondingly minute concentrations of Ca^{2+} and Mg^{2+} . The pH of alkaline lakes is usually in the range of 10–11; in some evaporation ponds, it can rise up to 12 (Oren, 2002). Microbial isolates from alkaline hypersaline lakes include the archaea *Natronomonas* sp., *Natronococcus* sp., *Natrialba* sp., and bacteria of the genera *Halomonas*, *Chromohalobacter*, *Spirulina* (the latter is known as nutrient for humans and animals) and others still to be characterized (Javor, 1989; Oren, 2002).

Halobacteria – Halophiles, Figure 1 Lagoons of a commercial salt-producing facility in Namibia, close to the ocean. Red-colored lagoons contain mainly haloarchaea; green color is due to halotolerant algae or cyanobacteria.

Halobacteria – Halophiles, Figure 2 Scanning electron micrograph of cells of *Halobacterium salinarum* NRC-1 (left) and *Halococcus salifodinae* DSM8989T (right). Bars, 0.5 μm. (Photographs were taken by C. Frethem (left) and G. Wanner (right).)

From the Deep Lake in the Vestfold Hills of Antarctica, a psychrophilic archaeon, *Haloarubrum lacusprofundi*, was isolated. Deep Lake has a salinity that is ten times higher than that of seawater (3.6–4.8 M). The lake remains ice-free throughout the year, with water temperatures fluctuating between +10 and –15°C and remaining below 0°C for ~8 months of the year. The microbial diversity in Deep Lake is extremely low and is dominated by haloarchaea, with apparently low numbers of *Dunaliella* sp. and bacteria (of the beta- and gamma-proteobacteria) present in the sediment (Cavicchioli, 2006).

Less explored and unusual hypersaline habitats are represented by anoxic brines near the bottom of the sea, for example in the Mediterranean deeps, which contain saline brines almost saturated with magnesium chloride, and where a wide diversity of novel archaea and bacteria was detected (van der Wielen et al., 2005).

Another environment for halophilic microorganisms are ancient salt deposits; recent reports have described the presence of haloarchaea in Triassic and Permian salts (summarized in McGenity et al., 2000; Stan-Lotter et al., 2004). These viable microorganisms were consistently isolated from surface-sterilized crystals obtained from freshly blasted rock salt or deep drilling bore cores, suggesting that these were survivors from the original depositional event (see Chapter “*Deep Biosphere of Salt Deposits*”).

Finally, halophilic viruses have been detected, which were released from bacteria and archaea; in addition, free virus particles were found by electron microscopical examination of the Dead Sea and in Spanish saltern ponds (Oren, 2002). The viruses (also called bacteriophages) were equally dependent as their hosts on high concentrations of salt for their structural stability. There is little information on the role of viruses in natural environments; suggestions which were made involve ecological functions in controlling the sizes of microbial communities (Oren, 2002). A website with pictures of haloviruses from

the laboratory of M. Dyll-Smith is available: <http://www.microbiol.unimelb.edu.au/people/dyallsmith/research/haloviruses/>

Classification and genomics

Halophilic means salt-loving and this term, often as the prefix hal- or halo-, has been in use since the 1930s. Therefore, members of the bacteria as well as the separate prokaryotic group archaea, which was identified only in the 1970s, may contain such prefixes in their names. Some confusion may arise from this nomenclatural convention, since, for example, the genus with the name *Halobacterium* belongs to the halophilic archaea (or haloarchaea), not to the bacteria.

The number of recognized haloarchaeal genera has increased to 26, according to the International Committee on Systematics of Prokaryotes (<http://www.the-icsp.org>) and the number of validated species at this time is 86. Main taxonomic criteria for the identification and recognition of haloarchaea are the sequence of the 16S rRNA genes and the composition of their characteristic membrane polar lipids, which are unique ether-linked phosphoglycerides (see Fendrihan et al., 2006, for a recent overview). The complete list of required and recommended criteria for the formal identification and recognition of haloarchaeal species was proposed by Oren et al. (1997). For halophilic bacteria belonging to the large family *Halomonadaceae*, a similar list of specific characteristics, which has been revised recently, can be consulted (Arahal et al., 2007).

Five genomes of haloarchaea have been completely sequenced, that of *Halobacterium salinarum* NRC-1, the related strain *Halobacterium salinarum* R1, *Haloarcula marismortui*, *Natronomonas pharaonis*, and *Haloquadratum walsbyi*, and one genome of a halophilic bacterium (*Salinibacter ruber*). The website <http://www.ncbi.nlm.nih.gov/sites/entrez> lists all genome projects, whether complete or still in progress, including references

and detailed descriptions. Comparisons of genomes continue to provide insights about similarity and differences between archaea and bacteria and about the early evolution of prokaryotes. They have, for example, proven that the adaptation mechanism of keeping a high internal salt concentration (see next paragraph) is not unique to archaea, as was thought before, but is used also by *Salinibacter ruber*; this common property as well as some other characteristics suggests the possibility of early lateral gene transfers between prokaryotes (Velieux et al., 2007).

Adaptations to high salinity

Most halophiles are unable to survive outside their high-salt native environments. Some species of the haloarchaea are so fragile that when placed in distilled water they lyse within minutes from the change in osmotic conditions (Grant, 2001). This reflects a general adaptation of the cells' entire intracellular machinery to high concentrations of cations. Halophilic and halotolerant organisms have to expend energy to exclude salt from their cytoplasm to avoid protein aggregation ("salting out"). Two different strategies are known to be used to prevent desiccation through osmotic movement of water out of their cytoplasm, and both work by increasing the internal osmolarity of the cell. In the first, organic compounds, termed "compatible solutes," are accumulated in the cytoplasm; this strategy has been found in many halophilic bacteria and also in some archaea, yeasts, algae, and fungi (Galinski, 1995). Compatible solutes are neutral or zwitterionic and include amino acids, sugars, polyols, betaines, and ectoines, as well as derivatives of some of these compounds; they can be synthesized de novo or taken up from the environment (Galinski, 1995; Grant, 2004). The second adaptation involves the selective import of K^+ ions into the cytoplasm, which can reach internal concentrations of 5 M. This adaptation is restricted to the moderately halophilic bacterial order *Halanaerobiales*, the haloarchaeal family *Halobacteriaceae*, and the extremely halophilic bacterium *Salinibacter ruber* (Oren, 2002). Most proteins of haloarchaea and also of *Salinibacter* contain a large excess of acidic amino acids (glutamate and aspartate) and a low content of basic amino acids (lysine and arginine; Lanyi, 1974; Oren, 2002); these features are thought to represent a specific adaptation to high levels of salt (Mevarech et al., 2000; Oren, 2002). In contrast, the action of compatible solutes is much less specific, with little or no adjustment of intracellular macromolecules required, which is in line with the observation that these compounds act as general stress protectants against heating, freezing, and drying (see Oren, 2002, and references therein).

Conclusions

Halophilic organisms occur in all major groups on the tree of life (see Oren, 2007) and even halophilic viral representatives are known. Halophilic microorganisms in particular

may be found on earth in almost every hypersaline environment – tropical to polar, terrestrial to submarine, acidic to alkaline, or aerobic to anaerobic (Javor, 1989). Initially a little-studied group of microorganisms, halophilic bacteria and archaea have proven to be of interest for life sciences and earth sciences as well; their investigation has resulted in major insights for molecular biology, genomics, biogeochemistry, and – most recently – astrobiology.

HAPTOPHYTES

Haptophytes (Haptophyta, Prymnesiophyta) are unicellular chlorophyll a and c containing algae with complex plastids derived from secondary endosymbiosis (“red lineage”) (see entry “*Symbiosis*”). They occur principally as solitary free-living motile cells that possess two smooth flagella, unequal in length in the Pavlovophyceae and more or less equal in the Prymnesiophyceae. Haptophytes inhabit littoral, coastal, and oceanic waters and are important primary producers in many aquatic environments. Within the haptophytes, the so-called coccolithophores (coccolithophorids) evolved the ability to control the intracellular calcification onto organic plates and the assembly of the mature calcium carbonate (calcite) scales (coccoliths) at the cell surface. These forms have been significantly contributing to the deposition of calcium carbonate in marine waters since the Mesozoic, today accounting for about a third of the total marine CaCO₃ production. In modern and ancient sediments, haptophyte-derived organic matter contributions can be specified by distinctive lipid biomarkers (alkenones), whose unsaturation patterns also provide a paleo-thermometer for past surface water temperatures (see entry “*Biomarkers (Molecular Fossils)*”). For further details, please see entry “*Algae (Eukaryotic)*.”

²Goethe-University Frankfurt, Frankfurt a. M., Germany

Definition

Histology is the biological science concerned with the minute or microscopic structures of cells, tissues, and organs of animals, plants, and fungi, in relation to their function, and any organismic constructions produced by living individuals or symbiotic assemblies of living organisms.

Biopsy is the sample of an organism or part of a tissue that is processed for histological investigations.

Fixation serves the inhibition of all vital processes by special chemicals that also preserve and prepare organic matter for further histological or morphological investigations.

Mineralization is the process by which organic components of organisms are impregnated or replaced by inorganic material and converted to mineral matter.

Staining is the chemical reaction of particular laboratory chemicals (stains and dyes) with tissue components and materials of the samples.

Introduction

The term histology was coined by C. Mayer in 1819 as a part of the scientific discipline comparative anatomy (Mayer, 1819). Histological investigations, concerned with the minute structures of cells, cell organelles, intra- and extracellular fiber arrangements, and tissue components and organs in relation to their function, are usually done by light microscopy. Since the invention of the microscope by Leeuwenhoek in 1668 (Palm and Snelders, 1983), the early histological technology (Gerlach, 1998) has experienced major improvement by the refinement of microscopes (Bozzola and Russell, 1999) and new methods of tissue preservation, sectioning devices, stains, and staining methods. Histochemical methods now permit to identify and localize intracellular components and enzymes within distinct and isolated samples (e.g., Bancroft and Gamble, 2007; Böck, 1989; Horobin and Kiernan, 2002; Mulisch and Welsch, 2010). Therefore, the studied structures, tissues, complete organisms, or any organismic compound have to be preserved from enzymatic decay, and then cut into sections of just a few microns thickness. The histological sections can vary between ultra thin sections (40–80 nm), semi thin sections (0.1–3.0 µm), thin sections (3–20 µm), and thick sections (more than 20 µm). While ultra thin sections could be investigated only by transmission or scanning electron microscopy (TEM), the others can be investigated with any light microscope. Afterward, these sections are

processed by various histochemical and biophysical techniques according to the aim of the study.

Geobiological samples usually do not consist of organic soft material, alone, like the above mentioned biological materials, but they are often composites of hard inorganic and mineralized organic material, with nearly all biological components converted to inorganic matter. Some geobiological samples are compositions of both, organic and inorganic materials, such as bio films growing on hard substrates, or sessile organisms that adhere to hard substrates like corals, sponges, lichens, or fungi. These samples therefore can seldom be histologically processed like biological material via paraffin embedding and sectioning with traditional microtomes. Special procedures and mechanical devices (like saw microtomes, annular saws or cutting/grindings systems) are necessary to produce sections of geobiological samples (e.g., Hoffmann et al., 2003). By means of special polishing machines, like the ultramill or lapping machines, sections or slices of these sections can be studied by distinct microscopical methods, for example under fluorescent light, X-ray-mappings and topographic element analyses (Janssens et al., 2000) can identify the outline of the biological compounds and their environment, and they may also serve as a biomarker; harsh biochemical treatment can isolate the organic from the inorganic components, but often destroy the original context. Histological analyses may provide tools to identify the biological components even if their former structural context has decayed (Wrede et al., 2008), or help to analyze particular processes or compositions (Neuweiler et al., 2007). Principally these results must be “calibrated” by means of histological investigations of recent tissues in order to understand organ structure and its function (Young and Heath, 2000).

This entry reviews the state of the histological methods and offers the modifications necessary to topographically investigate geobiological samples. *For clarity, this latter information is given in italics.*

Methods

Different from biochemical investigations in the broadest sense, histological analyses are concerned with samples, where the structures and their topographical context are preserved or known before biopsies are taken and only in a controlled way modified by procedures according to the specific aim of the study.

For histological processing of tissues or any other organic compounds, all vital functions have to be stopped by fixation, in order to preserve a distinct structure within or more often isolated from its natural environment. *In geobiology this process often is “history,” but must be known to understand the given results of further analyses.* Usually, the biological samples are embedded into a special medium which provides particular mechanical properties that allow sectioning in the appropriate thickness. The sections are then placed on glass slides or cover

slips, afterwards stained by special chemicals and dyes that have affinities to particular tissues or histological structures. The staining allows the differentiation of cell structures, various types of cell surface and skeleton assemblies, filaments or fibrillar components (e.g., collagenous fibers, elastic fibers, or reticular fibers), tissues, and even complete organs or pathological and genetic modifications of the various structures. Under the microscope the results can be observed and – most often after a thorough comparison to reference samples – evaluated and interpreted.

In geobiology, the selective staining of minerals prevails, although protein staining has been successful in various studies. The major problem in geobiology is that mineralized samples are too hard for conventional section procedures and therefore special preparation methods are necessary (see also below, paragraph “Embedding”). Accordingly, often only the surface of sectioned samples is accessible to the staining which limits the differentiations of components. Structural analyses of biological compounds have to refer to similar structures or organs histologically known from recent specimen. Therefore, histology in geobiology has to refer to a biological histology (Robenek, 1995). Specialized methods are available which either demineralize the sample for showing the biological contents or dissolve the organic leftovers to investigate their “casts” in the inorganic surroundings. Often the resulting histologically processed specimens can be biophysically investigated, and topographic X-ray element mappings (Janssens et al., 2000) are often the method of choice to serve as biomarkers.

Fixation and infiltration

The process of fixation and infiltration of biological specimens is most crucial for the results and aims to stop any autolytic and bacterial decomposition. The most commonly used fixative is formalin; however, other fixatives (e.g., Bouin, Carnoy, Paraformaldehyde, potassium dichromate, chromic acid, or mercury-fixation) are necessary depending on the planned subsequent protocol. The choice of the fixative determines the results, since every fixative has assets and drawbacks for the preservation of particular histological structures and especially the binding sites for differential staining, e.g., in immunohistology. For biophysical analyses, the metal-free fixatives and also metal-free pre- and post-processing protocols are essential.

The fixation process, which is a chemical reaction, has to be controlled and stopped after a particular time that depends on type and size of the tissue, but also on environmental factors like temperature and air pressure. Afterwards the fixative must be removed following a special protocol, which takes care not to destroy structural characteristics (Böck, 1989).

Prior to embedding, the sample has to be slowly transferred to the final substance via several intermediate steps mixable with the respective embedding medium, e.g.,

for the paraffin/wax embedding dehydrants (ethanol, isopropanol, and methanol) and clearants (xylene, toluene, and xylene-replacing clearants).

In case of aerated tissues, it may be necessary to perfuse the sample with a prefix and process fixation and embedding continuously in a vacuum with fluid movement for a proper impregnation of all layers of the specimen.

In geobiology, fixation and conservation also plays a crucial role, since these chemical processes have to be balanced between the necessities for the mineralized and organic components of a geobiological sample (biofilms or water containing fossils; e.g., Desrochers et al., 2007). Every fixative generates chemical reactions, which sometimes may degrade or destroy either the organic or the mineralized components. Accordingly, empirical studies have to be performed before crucial samples are processed in order to ascertain whether the fixative may cause any problems for either the soft or hard tissues of a particular type of samples.

Embedding

Embedding of histological material is performed in order to provide a mechanical stable and hard entity, which can be sectioned to various coherent thin sections. The sections should enable a spatial reconstruction of the original sample after differentiating analyses. The composition of the specimen and the histological program are decisive for the embedding methods of choice. The most common material for tissue embedding is paraffin (wax-embedding), also embedding in celloidin and resin. If the tissues under study are more or less soft (which means without any calcareous or other mineralized structures), the paraffin embedding is the best choice. Celloidin embedding takes much time and is useful for very sophisticated questions (e.g., embedding of complete brains or very large organs). Plastic embeddings are the best choice if the biopsies contain mineralized structures, such as calcium carbonate, calcium phosphate, and silicate, or if organismic components adhere to rocks or other hard substrates, like for example biofilms.

Therefore, these latter embedding methods lend themselves for geobiological samples, which then can be processed like biological material. For resin embedding (Howat et al., 2007) one can choose between epoxy-embedding, methyl-methacrylate-embedding, or glycol-methacrylate-embedding. Various products are commercially available (Obenauf et al., 2007), all of them have well-documented assets and drawbacks. The most drawbacks of plastic embeddings can be seen in their high costs of time and money. On the other hand, resin embedded samples can be sectioned, sawed, milled, or polished by use of various microtomes, saws, milling, or polishing machines.

Sectioning

Whole mount samples can only be investigated from their outer surface. Analyses inside the samples need dissection

with preferably minor destruction of the structural context. In general, penetration of staining chemicals is enhanced afterwards, and microscopic and biophysical inspection is improved as the spatial resolution corresponds to the thickness of the section. Several problems may arise from inappropriate section procedures:

- The samples may be too brittle and break. This effect is reduced by pre-treatment procedures like decalcification or demineralization, also choosing another type of embedding medium may help possibly combined with different section techniques, e.g., a vibrating knife or sample cooling by a special refrigerant device.
- The sections are heavily distorted. A proper selection of the microtome, cutting angle, and cutting velocity may improve the result. The sections may stretch, for example, after floating on a warm water bath about 10°C below the melting point of the embedding wax.
- The requested thickness requires different blades, which cannot be used “universally,” even if section series of varying thickness are necessary for the protocol. For example, thick sections need a hard metal blade, while semithin- and ultrathin sections can be produced only by means of glass or diamond knives.

Biological samples, which are embedded in paraffin or resin, can generally be sectioned by a special device, a microtome. Some microtomes are equipped with a motor-driven support, both for controlling the section thickness as well as the force of the blade. Several types of microtomes are available, each optimized for variably embedded samples: Paraffin embedded samples can be sectioned by sled microtomes or rotary microtomes equipped with metal knives. Resin embedded samples need microtomes which have a special retraction mechanism, to avoid mechanical damage of the knife and the sample. The blades are either manufactured of especially hardened steel for sections between 5 and 30 µm, for semi thin sections (2–5 µm) and ultra thin sections (about 40–100 nm) glass or diamond knives must be used.

Hard materials, like mineralized geobiological probes, cannot be sectioned by conventional microtomes unless the samples have been pre-treated: decalcification or demineralization by different chemicals. While these procedures may cause uncontrolled damage, when applied to the unsectioned samples, preferably control material should be preserved to evaluate the original structural context. Therefore, careful special section devices like diamond milling, saw microtomes, annular saws, or section/grinding-systems especially optimized for this purpose should be applied. About 30 µm thick sections of rather large samples can be achieved by these methods. The sections or grinded pieces can then be further processed, and also partly preserved for subsequent evaluation.

Another method, available since several years, is the laser microtome which may contact free isolate minute samples out of the otherwise untreated entity. The samples must neither be pre-treated nor embedded. Section thickness ranges between 10 and 100 µm. Special

devices allow even for the isolation of minute tissue pieces like a single cellular nucleus.

A satisfying section quality requires a long time of experience especially to decide for the most appropriate procedure. While continuously new embedding products are commercialized, only little has changed concerning the basic techniques of standard microtomy, which is taught as a component part of the education of laboratory and technical assistants.

Mounting

For further histological processing, the sections must be mounted, most often on glass slides or on grids coated with a special synthetic film.

The major difficulty is the choice of the best possible sticking procedures in order to prevent both, a floating resp. a loss of the sections during the staining protocol and undesired background staining by the glue. While before often unreliable “home-made” coating procedures, e.g., by chromic sulphate or polylysine, were used, now various types of pretreated glass slides are commercially available, they have been optimized for selected histological procedures. Thick sections, e.g., sections that are produced by saw microtomes or cutting/grinding-systems, have to be glued to object slides by special sticking resins that, e.g., harden with ultraviolet light; in this aspect, histological sample preparation is quite similar to the preparation of geological thin ground-sections.

Biophysical analyses of geobiological samples requires mounting according to the planned technique (see list of Handbooks of the suppliers). In, for example, X-ray investigations (micro fluorescence analyses), the mounting must be free of auto fluorescence; the sometimes long lasting measuring intervals need a stable non-vibrating mechanical stability.

Staining

Multiple histological staining methods allow identifying cellular structures, tissue components, and organ systems, also enzymatic processes and involved macromolecules. It is even possible to clearly differentiate between organic and inorganic material as well as decaying from living material by selective marking of minerals and molecules.

Stainings can be performed by use of natural stains and dyes or by chemicals often designed for certain projects. New fields of histological analyses have been launched by immunohistochemical stainings combined with fluorescent markers which are very selectively binding to particular proteins. Differential and double stainings, also section series with alternatively stained sections, have revealed important insight into basic cellular processes, information processing, and also pathological resp. genetic changes. The standard protocols are well documented including their modifications for the application to tissues of various origins.

For any staining it is necessary that the structures that should be stained are free of any embedding media. This means that for standard-histology the paraffin has to be removed by special procedures so that the staining chemicals can react with the tissues. If samples are embedded in resins, this process is more crucial and difficult; several resins cannot be removed and accordingly only the surface of the section provides reactive structures for staining.

The staining of cellular structures and tissues is based on chemical affinities of the stains with particular tissues resp. tissue components. In many cases, a particular pretreatment is necessary for adequate results. Pretreatments may be, for example, mordants, which modify the stain so that it reacts with the tissue or modifies the tissues so that the stain can react with the tissue. In some cases mordants generate a reaction that transformed the water soluble stain into a water- and alcohol-stable lacquer. This chemical reaction can, for example, be induced by metal ions like tungsten or molybdenum or by alkali ions like lithium, sodium, or barium (Böck, 1989; Burck, 1988).

Stainings are usually composed of three steps: in the first step cellular structures like nuclei, etc., are stained. In the second step cell plasma and some extracellular structures are stained, and in the third step the surrounding matrix is stained.

As a result of the staining, the nuclei, cells, various fibers, and other structures or chemical components in a tissue have particular colors that allow differentiation and several diagnostics. Some stainings also provide particular optical characteristics to tissues; they may for example provide polarizing effects to the tissue. Other procedures provide fluorescence-effects or particular ultra-violet-effects of the polished surface and allow further investigations (Figures 1 and 2).

While traditional stainings induce a chemical reaction within tissues and may stain in an unselective way (Horobin and Kiernan, 2002), immunohistology (Polak and Noorden, 2003) selectively marks specific epitopes, proteins, and molecules bound to membrane or subcellular structures. Traditional and immunohistochemical analyses under the light microscope meet the limits of resolution at magnifications of about 1,200×; therefore, immunohistological methods have been upgraded for analyses under the TEM, either by pre-embedding or post-embedding staining protocols.

While traditional stainings are used for topographic and micro anatomical investigations, immunohistological stainings are used to understand the functional context of molecular processes and to allocate the regions in which these processes take place in an organism or in a tissue.

These refined immunohistological staining methods have also been applied to sections of geobiological samples. The analyses could demonstrate biological compounds, thus serving as biomarkers, and in some cases even disclose the genetic origin of the fossilized organisms.

Histology, Figure 1 Cross section of a human long bone under different microscopic optics (thin-ground section of a non-demineralized sample). (a) Under through light with minimal color saturation; (b) same illumination with maximum color saturation; (c) differential interference contrast (After Nomarski). Already without staining procedures characteristic structural details and varying densities can be identified. (a–c same magnification.)

Histology, Figure 2 Section series through a chondral ossification zone of a demineralized porcine long bone after various differential histological staining procedures (Protocols according to Böck et al., 1989; Young and Heath, 2000). (a) Masson Goldner A; (b) Masson Goldner L; (c) Masson Goldner ResF A; (d) Masson Goldner ResF L; (e) Crossmon A; (f) Crossmon L; (g) Azan after Geidis; (h) Movat Pentachrome; (i) Safranin Fastgreen. The layers of young bone (upper area), cartilage (middle area), and secondary ossification area (below) can be analyzed concerning their different structural details (a–i same magnification).

Conclusion

Geobiology is defined as field of science which analyses the interaction of the environment with living matter. Mainly fossilized samples are investigated concerning their systematic relationship and – even more – the origin of this specific form of life. Research results can find their application not only in a better understanding of our life on earth, but also in exploring putative extraterrestrial biology. Another aspect is the transfer of basic sciences to various aspects of biomedical research like the synthesis or degradation of bones and teeth or the control of biogenic mineralization processes. All these research topics cannot be planned and performed or adequately evaluated without a thorough knowledge of the biological structures mainly based on the comparison of living and fossilized specimen. Histology delivers the methods to topographically analyze organisms, organs, tissues, and even molecules. Their modifications by environmental or biogenic processes can be recognized by the investigation of their complex interaction.

Perspectives

Histological investigations provide a huge field of research for biology and geobiology. Both fields have to be combined, since geobiological samples often can only be interpreted with reference to known biological samples. Some examples are histological sections of dinosaur bones or teeth that have to be compared to bones and teeth of recent organisms, others are the discoveries at special fossil-sites, like the Messel pit, the Burgess-Shale, the rocky Hunsrück region, etc., which may provide interesting information about fossilized microscopic structures. And even the investigation of recent samples like biofilms or coatings is of major relevance to understand their composition and emergence in order to discriminate between biogenic and abiotic origin.

Summary

Histology provides methods to topographically investigate the structure of cells, tissues, and organs down to the molecular level, especially in geobiology as reference to recognize, for example, the phylogenetic origin and age and also as a basis to analyze biological in comparison to bio geological turnover processes, which induce structural changes via environmental and climatic conditions.

HOT SPRINGS AND GEYSERS

Brian Jones¹, Robin W. Renaut²

¹University of Alberta, Edmonton, Alberta, Canada

²University of Saskatchewan, Saskatoon, SK, Canada

Definition

A *hot spring* is a discharge of hot (>35 – 40°C) water from a vent at the Earth's surface.

A *geyser* is a hot spring characterized by intermittent, turbulent discharges of boiling water and steam.

A *sublacustrine hot spring* is a hot spring that discharges from the floor of a lake.

Introduction

A hot spring is characterized by discharge of hot water from a vent. There is, however, no universally accepted definition of “hot” and the temperature for distinguishing a “warm spring” from a “hot spring” remains contentious (Pentecost et al., 2003). In general usage, a hot spring is one with vent water temperature between about 40°C and boiling point (Renaut and Jones, 2000). It must be remembered, however, that boiling temperature changes with altitude; thus, boiling in Yellowstone National Park occurs at $\sim 92^{\circ}\text{C}$, whereas in New Zealand geothermal areas, which lie closer to sea level, it is at $\sim 100^{\circ}\text{C}$.

The term “geyser” is derived from “Geysir,” located in southwest Iceland. First mentioned in historical records from 1294, the Icelandic word “geysir” means “gusher” or “one who rages.” Accordingly, a geyser is regarded as hot spring that is characterized by intermittent, turbulent discharges of boiling water and steam (Bryan, 2005, 2008).

Geysers and hot springs are end members of a continuous spectrum that includes “intermittent springs” that experience periodic overflows but never erupt, and “pulsating springs,” “perpetual spouters,” or “ebullient springs” that are characterized by continual eruptions. Some hot springs discharge on the floors of lakes and in caves.

Distribution

Hot springs and geysers are found on every continent except mainland Antarctica (Waring, 1965). Many hot springs and geysers, known from historical records, have ceased activity because of natural and anthropogenically induced changes to their plumbing systems. Yellowstone National Park, USA., El Tatio located high in the Andes of northern Chile, the Taupo Volcanic Zone on the North Island of New Zealand, Kronotski National Park in Kamchatka in eastern Russia, and Iceland are the largest known geothermal fields with numerous hot springs and geysers. Bryan (2008), for example, estimated that more than 50% (~ 500) of known geysers are located in Yellowstone National Park, with another 385 in the other four major geothermal areas. Low-enthalpy hot springs that discharge at maximum temperatures of about 35 – 60°C are much more common.

The plumbing system

The hot water discharged by a hot spring or geyser is the final, surface expression of a complex system that involves water, a heat source, and an intricate underground plumbing system. The water is derived from meteoric waters that have seeped deep into the Earth's crust, supplemented in some regions by connate, magmatic, or metamorphic waters. Irrespective of its origin, some spring or geyser water may come from depths of ~ 4 km where it has been magmatically heated to temperatures of $>225^{\circ}\text{C}$. In other settings, however, meteoric waters may only penetrate to shallow depths before being expelled from a low-enthalpy spring vent. The plumbing system of a hot spring is unrestricted and allows continuous movement of water to the surface. In contrast, a geyser has a restriction within its plumbing system, commonly a sinter caprock that precludes continuous vertical flow. The configurations of these plumbing systems remain unknown because of the difficulties in accessing them. Nevertheless, schematic depictions of vast underground, water-filled chambers are probably incorrect. Instead, it seems that the plumbing systems are formed of complex networks of faults, fractures, small cavities, and strata with variable permeability. Geysers are less common than hot springs because of the special plumbing system requirements.

Water trapped below a restriction in a geyser plumbing system will be heated by steam that is moving upwards from deeper parts of the system. The reservoir will then empty as the trapped superheated water is violently discharged. Such an eruption will continue until the reservoir is emptied. The magnitude, frequency, and duration of the eruption depend on reservoir size, the rate of heat transfer, and the rate at which water refills the system once emptied by the eruption. By necessity, therefore, geysers can only exist if the bedrock can withstand the pressures created by the steam and if the bedrock is permeable enough to allow rapid reservoir replenishment.

Water acidity and composition

Most springs and geysers discharge alkaline water with a pH ≥ 7 . Most high-enthalpy geothermal areas (e.g., Taupo Volcanic Zone of New Zealand), however, include springs that discharge acidic waters with a pH ≤ 7 and commonly < 3 . The acidic spring waters usually form through oxidation of H_2S and (or) SO_2 that move upward with steam released upon subsurface boiling and are then absorbed by shallow groundwaters. The pH of the spring water is important because it controls the type of biota living on the discharge apron and the minerals that are precipitated in and around the spring vent.

The composition of the spring water is mainly a function of reactions that take place between the bedrock and the water as it circulates through its plumbing system. In this context, the composition of the bedrock is critical because that will determine the elements that can be transferred to the groundwater.

Precipitates

The type of precipitate that forms in association with a hot spring or geyser is fundamentally controlled by water composition. Thus, waters containing SiO_2 may produce opal-A ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) (Walter, 1976; Cady and Farmer, 1996; Jones et al., 1997), waters containing CaCO_3 may give rise to calcite and (or) aragonite (Renaut and Jones, 1997), and acidic waters containing Fe may produce jarosite [$\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$], lepidocrocite ($\gamma\text{-FeOOH}$), and (or) hydrous ferric oxide (mainly goethite: $\alpha\text{-FeOOH}$) (Jones and Renaut, 2007).

Silica

Water discharged from hot springs and geysers commonly has a high content of dissolved SiO_2 (e.g., Geysir with ~ 500 ppm SiO_2). With cooling and evaporation, the waters become supersaturated with respect to amorphous silica, and non-crystalline opal-A containing 1.5–15 wt% H_2O (as molecular water and hydroxyl) is precipitated. Siliceous sinters precipitated around hot spring and geyser vents have been called “geyserite.” Morphologically similar to stromatolites because of their thin laminae and botryoidal structures, geyserite was considered abiogenic because it lacked evidence of permineralized microbes and grew in hot waters that were presumed sterile (Walter, 1976). Scanning electron microscope imaging of “geyserite” collected from the vent areas of many springs and geysers on the North Island of New Zealand, Yellowstone, and elsewhere, however, revealed the presence of well-preserved microbes (Cady and Farmer, 1996; Jones et al., 1997, 2001) and thereby demonstrated that some “geyserite” was not abiogenic.

Sinter precipitated in hot springs and geysers commonly contains significant quantities of other elements, including Fe, Al, Au, Ag, and As. Orange siliceous sinters on the submerged shelf around Champagne Pool, Waiotapu (Figure 1b), for example, are rich in As, Sb, Tl, and Hg, and contain ~ 100 ppm Au and ~ 330 ppm

Ag. Such trace element concentrations commonly appear to be related to microbial adsorption and complexation.

Calcite/aragonite

Folk (1994) suggested that calcite as opposed to aragonite precipitation in hot spring and geyser systems is controlled primarily by water temperature (calcite $< 45^\circ\text{C}$ > aragonite) and (or) Mg:Ca ratio (calcite $< 1:1$ > aragonite). Nevertheless, both calcite and aragonite are found around some hot springs and geyser vents where water temperatures are $> 45^\circ\text{C}$. Spring waters discharged with high PCO_2 may, through rapid CO_2 degassing, quickly attain very high levels of supersaturation with respect to CaCO_3 . This commonly seems to be responsible for calcite and aragonite precipitation even if the waters are $> 75^\circ\text{C}$ and have a Mg:Ca ratio of $< 1:1$. Bizarre and unusual crystal morphologies also seem to be consequence of the high saturation levels.

Fe-rich precipitates

Non-crystalline hydrous ferric oxides (HFO), lepidocrocite, alunite, jarosite, pyrite, and clay minerals (kaolinite) are commonly precipitated in acidic, hot spring systems (Figure 1e). Some non-crystalline HFO contains high concentrations of other elements, including As, Mn, Cu, Zn, Cd, Pb (Jones and Renaut, 2007). Precipitation of the different Fe-rich minerals appears to be related to subtle changes in the pH and sulfate (SO_4^{2-}) of the spring waters.

Biota

Hyperthermophilic microbes, which thrive in waters with a temperature $> 75\text{--}80^\circ\text{C}$, include Bacteria and Archaea (Sheehan et al., 2005). Most Archaea are in the form of cocci, rods, or discs (Stetter, 1996, his Table 3). These non-distinctive morphologies coupled with the problems of laboratory culturing due to their poorly known growth requirements and nutritional needs have made species identification difficult. 16S rRNA sequencing, however, has shown that a diverse array of hyperthermophilic Bacteria, and Archaea thrive at high temperatures and extremes of pH, redox state, and salinity (Stetter, 1996; Kvist et al., 2005). Among the Bacteria, *Aquifex pyrophilus* and *Thermotoga maritima* thrive up to 95°C and 90°C , respectively. Among the Archaea, members of *Pyrobaculum*, *Pyrodictum*, *Pyrococcus*, and *Methanopyrus* survive in temperatures up to 100°C . The thermoacidophile *Sulfolobus*, for example, thrives in sulfur-rich hot springs at a pH of 2–3 and temperatures up to 90°C .

An easy way of collecting microbes that live in the dangerous environs of hot springs/geysers is to place sterile glass slides in the water for 24–72 h. Microbes quickly colonize such substrates and remain attached once the slides are extracted from the hydrothermal waters.

Microbe preservation

Mineralized microbes are commonly found in precipitates that form in hot spring and geyser systems (Figure 2).

Hot Springs and Geysers, Figure 1 Hot springs and geysers in the Taupo Volcanic Zone on the North Island of New Zealand (a, b, e, f) and El Tatio, northern Chile (c, d). (a) Prince of Wales Feathers and Pohutu during eruptive phase. Note silica precipitates on surrounding Geyser Flats. Whakarewarewa, Rotorua. (b) Margin of Champagne Pool showing exposed siliceous sinters (right) and submerged shelf covered with orange, gold- and silver-rich siliceous sinter. Water has a constant temperature of 75°C and pH of 5.4. Waiotapu geothermal area. (c) Siliceous sinter forming around margin of hot-spring pool, El Tatio. (d) Streamers of filamentous microbes in outflow channel from hot-spring pool, El Tatio. (e) General view of spring in northern part of Waiotapu geothermal area, water temperature of ~80°C and pH of 2.1–2.4. Submerged reddish-brown precipitates formed largely of noncrystalline As-rich hydrous ferric oxide, poorly crystalline lepidocrocite, and crystalline jarosite. (f) Black coating around small hot spring ($T = 100^{\circ}\text{C}$, $\text{pH} = 2.0$) in Kerosene Creek area, north part of Waiotapu geothermal area formed of bitumen generated by the spring system.

Such mineralization, which may involve replacement of the organic tissues and (or) encrustation around the microbes, must take place before the microbes are lost through decay. Microbe preservation is common in non-crystalline precipitates (e.g., opal-A, HFO) but rare in crystalline precipitates (e.g., calcite, aragonite, jarosite), possibly because the former generally precipitate at a faster rate than the latter and organic materials are less prone to destruction by crystal growth.

The microbes can play an active role (i.e., they mediate precipitation through modification of their microenvironment) or a passive role (i.e., they act as templates for precipitation by having nucleation sites on their surfaces) in their own mineralization. Experimental work and interpretation of naturally mineralized microbes indicate that microbes are probably passive during their own mineralization. There is, however, some evidence that some microbes may exert some influence over the initial pattern of opal-A precipitation (Jones et al., 2004).

Hot Springs and Geysers, Figure 2 SEM photomicrographs of siliceous microbes found in Champagne Pool (a, b; $T = 75^{\circ}\text{C}$, $\text{pH} = 5.2$) and Iodine Pool (c–g; $T = >80^{\circ}\text{C}$, $\text{pH} = 8.2\text{--}9.0$), North Island of New Zealand. (a) Silicified filamentous microbes in flocs that circulate in waters of Champagne Pool; (b) Silicified microbes in orange siliceous sinters from shelf around Champagne Pool (see Figure 1b); (c) Silicified rod-shaped microbes; (d and e) Rod-shaped microbes encrusted with different styles of opal-A spheres; (f) Filamentous microbes encrusted with layer of very small opal-A spheres and outer layer of larger opal-A spheres; (g) Silicified filamentous microbes encrusted with opal-A spheres of various sizes.

SEM imaging commonly reveals microbes that appear to be superbly preserved (Figure 2). It is, however, very difficult to identify such microbes in terms of extant taxa because most of the taxonomically important features are lost and DNA is generally not preserved. Thus, identifications must rely solely on morphological features such as general configuration, length, width, and the presence or absence of septa. The problem is compounded by the fact that most extant taxa are defined by DNA sequencing and may not have been imaged to show their morphology.

Conclusion

Hot springs and geysers are spectacular geological features that encompass a wide range of environments that are commonly characterized by extreme conditions (high T , low pH). Although opal-A, calcite/aragonite, and various Fe-rich deposits are the most common minerals precipitated from hot spring and geyser waters, these spring deposits commonly contain significant amounts of other elements, including Au, Ag, As, S, and many others.

Many hot spring and geyser systems are inhabited by a diverse array of microbes (archaea, bacteria, cyanobacteria, fungi, diatoms) that flourish in the warm discharge waters. Such microbes are frequently preserved, typically in opal-A, and thereby provide some insights into the nature of the microbial communities that inhabit these complex environs. Such fossils have received

considerable attention, as they are commonly considered analogous to silicified microbes that are found in much older deposits, especially those in the Precambrian.

HYDROGEN

Tori M. Hoehler
 NASA-Ames Research Center, Moffett Field, CA, USA

Synonyms

Dihydrogen; H₂

Definition

A diatomic molecule consisting of two atoms of hydrogen or its heavier isotopes.

Introduction

Hydrogen, the most abundant element in the universe by mass and number, exists on Earth principally in combination with oxygen (in H₂O) or carbon (in hydrocarbon and

organic compounds). The diatomic form, H₂ – although present in only trace abundance in the modern oceans and atmosphere – has played a central and evolving role in prebiotic and origin of life chemistry, in linking geochemical and biological cycles, and in shaping the structure, function, and interaction of microbial populations.

Geochemistry of H₂

Geosphere

H₂ is produced by the interaction of water and rocks through a variety of mechanisms (see review in Hoehler, 2005). Among processes that occur in widespread crustal rocks, perhaps the best known and most quantitatively important involves the reduction of water to H₂ by the ferrous iron components of rocks, which can be generalized as

with (FeO)_{rock} representing the ferrous iron component of igneous rock and (Fe₂O₃)_{rock} representing the ferric iron component of alteration minerals (e.g., magnetite). The capacity for H₂ generation via this mechanism is greatest in minerals with high ferrous iron contents, such as the ultramafic minerals olivine and pyroxene, where the process is called serpentinization. Basalts, with a lower ferrous iron content, have a smaller capacity to produce H₂, and granites (where ferrous iron-bearing phases are typically present as minor components) smaller still. The rates of hydrogen generation by water–rock reaction depend significantly on both temperature and the exposure of fresh surface area to water.

H₂ may also be generated via the radiolytic cleavage of water by α, β, or γ radiation produced during decay of isotopes in the host rocks (Spinks and Woods, 1964). Although oxidative species generated simultaneously during the process have potential to recombine with the hydrogen, radiolysis is nonetheless believed responsible for elevated H₂ concentrations (up to millimolar levels) in fluid emanations from a number of continental rock units. This mechanism is generally most important for granites, in which the content of the principal radiogenic elements U, Th, and K is generally highest among major crustal rock types.

Fracturing of silicate rocks may also serve to liberate H₂ that is formed either in solid-state reactions involving trace water impurities in the mineral lattice (Freund et al., 2002) or by direct reduction of water at the fractured surface (Kita et al., 1982).

Among these processes, serpentinization offers the greatest potential capacity for H₂ generation (per unit volume of rock), by orders of magnitude. However, multiple factors – including mineral composition, fluid flow and chemistry, temperature regime, and mechanical processing – ultimately determine which mode of lithogenic H₂ production may prevail in a given environment.

Atmosphere

H₂ is a trace component of the modern atmosphere, with an abundance of about 0.5 ppm (Levine, 1985) and a residence time of less than 1 year (Atkinson et al., 1979), but likely higher levels in the early atmosphere would have had important geochemical and biological implications. Atmospheric H₂ abundance reflects a balance of sources and sinks. Major source terms (excluding anthropogenic sources) include geological efflux (e.g., volcanic and hydrothermal vent emissions) and biological production. Sinks include oxidative atmospheric reactions, biological consumption, and escape to space. The low abundance of H₂ in the modern atmosphere reflects the dominance of oxidative reactions and biological consumption. The early, prebiotic Earth largely lacked such sinks and had a geological source term that was expectedly larger as a result of higher rates of geothermal emanation and a potentially more reducing character in the early mantle and crust (leading to higher H₂ concentrations in geothermal emanations). Estimates of atmospheric H₂ abundance at this time depend principally on theories regarding the oxidation state of the early mantle and crust, and consideration of the factors constraining H₂ escape to space. Even at the low end, these estimates generally predict atmospheric H₂ abundance of hundreds to thousands of parts per million, 3–4 orders of magnitude higher than in the present day.

H₂ itself is considered photochemically inert in the lower atmosphere (Levine, 1985), but it participates in a variety of reactions involving the radical products of photolysis. By serving as a sink for the oxidizing OH radical (Atkinson et al., 1979), and influencing the abundance of the atmospheric reductants H, HCO, and H₂CO (Canuto et al., 1983), H₂ directly affects the oxidation state of the atmosphere. As such, its relative abundance in the early atmosphere may have significantly affected redox speciation in the volatile nitrogen, carbon, and sulfur systems. In turn, this balance (e.g., the CH₄/CO₂ ratio, in the carbon system) affects the atmospheric radiation budget (through differing efficiencies of IR absorption), the potential for formation of photochemical hazes (Sagan and Chyba, 1997), and the formation and stability of simple organics in atmospheric chemical processes.

Above and beyond its role in buffering the oxidation state of the atmosphere through chemical interactions, escape of hydrogen to space can contribute to the irreversible oxidation of the planet, by carrying electrons out of the system (Walker, 1977). This process occurs at low rates in the modern, oxidized atmosphere, where the low abundance of H₂ results in low escape rates. However, H₂ escape from an early atmosphere containing orders of magnitude higher H₂ concentrations may have contributed substantially to the overall oxidation of the planet.

H₂ in prebiotic and origin of life chemistry

Prebiotic chemistry

The emergence of life must depend significantly on development of an inventory of abiotically generated compounds

that can serve as building blocks for biochemistry. Two of the most potentially important endogenous sources for such compounds – synthesis in hydrothermal vent settings and in atmospheric chemical processes – are known or inferred to depend strongly on H₂ for the yield and nature of compounds formed. In vent settings, H₂ from water–rock reactions is implicated as the reductant in Fischer–Tropsch type synthesis of methane, higher hydrocarbons, and simple organic acids, and is predicted to support the synthesis of amino acids and other prebiotic compounds. Miller–Urey type spark discharge experiments that simulate atmospheric chemical processes have a similar dependence that is demonstrated experimentally. For example, the yield of amino acids from simpler precursors in such experiments depends directly on the abundance of H₂, regardless of whether reduced or neutral starting materials (i.e., CH₄/NH₃ (Miller and Urey, 1959), or CO₂/N₂ (Schlesinger and Miller, 1983)) are used. Given its significance in prebiotic synthesis and atmospheric redox and photochemistry on the early Earth (see above), H₂ likely played an important overall role in establishing the environmental and chemical context from which life emerged.

Origin of life

Although the specific chemistry leading to the origin of life is not known, H₂ is proposed in some scenarios to have been a key component of the earliest metabolism (Wächtershauser, 1993). The oxidation of H₂ serves a potentially important dual purpose with respect to such metabolism, in yielding both reducing power and H⁺. Reducing power is necessary for generating organic biomolecules when the carbon source is CO₂. The establishment of H⁺ gradients (specifically, across membranes) can be used to store energy for subsequent coupling to biochemistry. Such dual-purpose chemistry underpins the metabolism of a wide range of modern organisms, including those thought to represent Earth's earliest life. The widespread availability of H₂ in geothermal emanations (e.g., Zobell, 1947; Elderfield and Schulz, 1996) and, presumably, in the prebiotic oceans and atmosphere would have made it a ubiquitous and reliable substrate on which to base the first metabolic chemistry.

H₂ and biology

The reversible oxidation of molecular hydrogen, $\text{H}_2 \rightleftharpoons \text{H}^+ + 2\text{e}^-$, is among the most widely utilized reactions in microbial metabolism. Hydrogenases, the enzymes which catalyze this transformation, are present in all three phylogenetic domains of life (Fenchel and Finlay, 1995; Vignais et al., 2001; Schwarz and Friedrich, 2003). They are particularly widely represented in the Bacteria and Archaea, including the most deeply branching and least derived lineages (Vignais et al., 2001; Schwarz and Friedrich, 2003), suggesting that, exclusive of a possible role in origin of life chemistry, H₂ metabolism has been an important contributor to biochemistry since the very early stages of evolution.

Since its emergence in metabolism, H_2 -based redox chemistry has come to be associated with an extremely broad range of microbial metabolic strategies, including oxygenic and anoxygenic phototrophy, anaerobic chemolitho- and chemoheterotrophy, and aerobic chemolithotrophy (Schwarz and Friedrich, 2003). H_2/H^+ can serve as electron donor, acceptor, or both, in these processes. This broad metabolic utility and versatility casts H_2 in a highly central role in the ecology of microbial communities, and in the geochemistry they mediate.

Lithotrophic communities

Organisms capable of H_2 metabolism can potentially be supported directly by geochemical production of H_2 (by, e.g., water–rock reaction or radiolysis). As such, they have potential to exist independently of energy input from light or the direct products of photosynthesis, oxygen, and organic matter. Such communities are therefore frequently envisioned as important contributors to Earth's earliest biosphere, to the rock-hosted subsurface biosphere, and, potentially, to subsurface life on other worlds. H_2 -based, photosynthesis-independent communities have been documented or inferred for a range of systems and H_2 -producing mechanisms, including vent fluids sourced in serpentinizing systems, basalt-hosted aquifers, and continental groundwaters bearing a signal of radiolytic H_2 production.

Heterotrophic communities

Systems driven by anaerobic decomposition of organic matter typically host a great diversity of H_2 -cycling organisms. Under anaerobic conditions, the complete degradation of complex organics cannot be accomplished by a single organism. Instead, the overall process is mediated, in a series of individual steps, by communities of microorganisms having different metabolic capabilities (Schink, 1988). The individual steps are linked through the transfer of electrons from one group of microbes to another, with H_2 serving as one of the most commonly employed molecular carriers of electrons. The pool of H_2 in such systems is typically characterized by low concentrations (subnanomolar to micromolar) and rapid turnover, with resultant residence times frequently in the range of seconds (Hoehler et al., 2002). Combined with a strong influence on the thermodynamics of reactions that produce or consume it (resulting from its typically high stoichiometric coefficient in such reactions), this effect casts H_2 as a key regulator of degradation pathways, community structure, and carbon and energy flow in such environments. Specifically, fluctuations in H_2 concentration are documented, in a process known as “interspecies H_2 transfer,” to affect the H_2 -cycling reactions by inhibition or stimulation, alteration of products, or even reversal (see review in Hoehler, 2005).

H_2 thus occupies a central role in anoxic ecosystems. Anoxia prevailed globally prior to about 2.4 billion years ago and continues to prevail in most organic-bearing

aqueous environments (including ocean, lake, and wetland sediments and animal digestive tracts). In the past and present, such systems represent a major control on the redox chemistry of the oceans and atmosphere, and the ultimate biological filter on material passing into the rock record.

Phototrophic communities

Most of the known photosynthetic microorganisms, representing both anoxygenic and oxygenic photosynthesis, possess a capability to engage in H_2 metabolism (Schwarz and Friedrich, 2003; Vignais et al., 1985). Most anoxygenic photosynthesizers, including representatives of the purple sulfur, purple non-sulfur, green sulfur, and green non-sulfur bacteria, can utilize H_2 as an electron donor for photosynthetic carbon fixation, and several are also capable of utilizing H_2 as an electron donor for the chemical reduction of inorganic oxidants. Some representatives of the cyanobacteria (oxygenic photosynthesizers) are similarly capable when operating in an anoxygenic photosynthetic mode of metabolism. H_2 is produced obligately during the conduct of nitrogen fixation and can also be photo-produced by the nitrogenase enzyme complex independently of nitrogen fixation. These capabilities, which occur widely among the cyanobacteria and anoxygenic photosynthesizers, are among the principal mechanisms being explored for biological production of H_2 as an alternative energy source. H_2 is also generated as a product of fermentation, a capability demonstrated in some cyanobacteria and purple sulfur bacteria. The fermentative mode of H_2 production appears to dominate the H_2 cycle in a variety of cyanobacterial “mats,” resulting in significant fluxes of H_2 out of the system (Hoehler et al., 2001; Hoehler et al., 2002). During the 1–2 billion years of Earth's history in which cyanobacterial mats dominated biological productivity on Earth, such fluxes may have contributed significantly to atmospheric H_2 levels and, by enhanced rates of H_2 escape to space, the overall oxidation of the planet.

Eukarya

Although not as widespread as in the *Bacteria* and *Archaea*, H_2 metabolism is also found in the *Eukarya*. In a variety of deep-branching anaerobic Eukaryotes, metabolism is tied to, or dependent on, an H_2 -based symbiosis with Bacterial or Archaeal partners (see review in Fenchel and Finlay, 1995). The driver of most of these symbioses is an H_2 -generating organelle, the hydrogenosome, which appears in some cases to be derived from a mitochondrion. These hydrogenosomes carry out fermentation, rather than oxidative phosphorylation, of pyruvate – and thereby produce H_2 . Microbial symbionts (which may include methanogens, sulfate reducers, and (in one case) photosynthetic purple non-sulfur bacteria) increase the energetic yield of this fermentation by consuming the end product H_2 . The symbiosis significantly enhances the growth of the host, and is, in some cases, so evolved that methanogen symbionts have lost their cell walls, and exhibit synchronization of cell

division with the host. Among photosynthetic Eukarya, green algae exhibit an active H_2 metabolism, and are considered a promising potential source of “biohydrogen” for alternative energy systems.

Summary

Hydrogen has played an important role in Earth's geochemistry and biology since the earliest stages of the planet's history. H_2 is produced by a variety of geochemical processes and is postulated to have been a significant component of the early, prebiotic atmosphere, where it had direct or indirect effects on atmospheric redox chemistry and radiation budget, and contributed to planetary oxidation by escape to space. Prebiotic and origin of life chemistry may have significantly involved H_2 , and its prominent use among deeply branching organisms in the tree of life reflects, at very least, a key role in metabolism since the biosphere's early stages. In the modern biosphere, H_2 biochemistry is associated with a broad variety of metabolic strategies, in all three domains of life. Although it now represents a trace component of the oceans and atmosphere, the significance of H_2 for planetary chemistry persists through its central role in the microbial world.

Black and White Smoker communities; Volcanogenic massive sulfide deposits – VMS

Definition

“Black smokers” represent extreme hydrothermal activities that are commonly located in deep sea environments

related with mid-ocean ridges and/or oceanic crust fault systems. Hydrothermal vent systems result from hydrothermal circulation of fluids controlling the transfer of energy and various matter from the interior to the surface of the oceanic crust, respectively the sediment surface. This hydrothermal circulation is a fundamental geological process and has been permanently influencing the chemistry of the oceans, and in consequence, also the composition of the entire earth crust. Seafloor hydrothermal activity has a major impact on the chemistry and life processes of the oceans (Parson et al., 1995; Humphries et al., 1995; van Dover, 2000). This entry focuses on volcanogenic massive sulfide deposits (VMS) and not on sedimentary exhalative deposits (SEDEX) – however, the boundary between both environments is not very strict. Massive sulfide deposits, hydrothermally altered rocks, and special communities of organisms are an important record of this process. Ancient seafloor hydrothermal activity is recorded in massive sulfides from the 3.5 GY-old Pilbara region of Western Australia (Barley, 1992). The new findings of hydrothermal vents with microbialites from 1.43 GY-old Precambrian rocks in northern China (Li and Kusky, 2007) are also of great interest. Within the Phanerozoic, roughly 20 sites are known with fossil hydrothermal vent communities (Little et al., 1998).

Geobiological notes

Hydrothermal vents have become one of the most fascinating fields of research in marine sciences. The recognition of complex vent communities consisting of organisms dependent on chemolithotrophy and extreme conditions of very high temperature, pressure, and chemistry at the ocean ridges was a great discovery (Humphris et al., 1995). There are many reasons to believe that life originated at hydrothermal vent environments in the late Hadean. However, only few publications are dealing with the fossil record of hydrothermal environments connected with preserved organism communities.

There are about 20 known Phanerozoic VMS sites with preserved hydrothermal vent communities, ranging from the Silurian to the Eocene. Most of these sites are found in the Ural Mountains and on Cyprus, some of them in Ireland, California, Philippines, and New Caledonia. All occurrences are linked to remains of oceanic crust (ophiolites). The investigation of vent systems is still a challenge, because the sites are normally small and most of them were destroyed during subduction of oceanic crust.

The vent communities contain assemblages of inarticulate and rhynchonellid brachiopods, gastropods, bivalves, and also monoplacophorans (Little et al., 1998; Kiel and Little, 2006). Remains of worm tubes are very characteristic and may be related to alvinellid polychaetes and pogonophorid-vestimentiferan chemotrophic worms. Most of the fossil taxa of the vent sites are endemic. However, the diagenetic loss of the original shell material makes it very difficult to classify the worm tubes in a modern

taxonomic scheme. Surprisingly, no arthropods were found at the fossil sites, whereas arthropods are very common in modern vent environments. There is an ongoing discussion on the origin of the vent fauna. New groups of organisms may have immigrated from the ambient environment and adapted to the extreme conditions of the vent sites and vice versa, some of them have left this environment. The origin of the vent faunas is thoroughly discussed in Kiel and Little (2006) and Little and Vrijenhoek (2003). Kiel and Little (2006) suggested that the mollusk seep faunas (hydrothermal vents and cold seeps) have a significantly longer evolutionary history than normal marine mollusks and show a tight taxonomic relationship with deep-sea mollusk faunas. The oldest known Phanerozoic hydrothermal vent is of Silurian age (Little et al., 1998). The discovery of the Mesoproterozoic (1.43 GY) hydrothermal vents in northern China was of great importance due to very well-preserved filamentous microbial communities forming massive sulfidic microbialites (Li and Kusky, 2007).

Conclusion

Fossil hydrothermal vent systems are known since the early Archaean and represent important geobiological environments. These environments have a significant key role in biological evolutionary processes. However, only few (ca. 20) sites are known worldwide in the Phanerozoic with preserved vents faunas. The oldest known fossil hydrothermal vent system with a metazoan community is known from the Silurian of the Ural Mountains (Little et al., 1998). Many of the vent organisms probably have a significantly longer evolutionary history than normal marine taxa (Kiel and Little, 2006).

Definition

Marine hydrothermal environments are one of the most extreme environments on Earth, yet they support highly productive biological communities over a wide range of physical and chemical environments. The following review is a general discussion of the types of microorganisms found in these different environments preceded by brief descriptions on hydrothermal fluid generation, mineral deposit formation, and microbial metabolism.

Introduction

The discovery of deep-sea hydrothermal vents and the lush biological communities associated with them in the late 1970s ushered in a new era for marine biologists. Prior to this discovery, life in the deep-sea was thought to be dependent on the settling of detrital material from the productive, overlying surface waters. While this is true for much of the ocean basins, the level of production observed at these newly discovered vent sites was too great to be supported by these mechanisms alone. It soon became evident that life in these environments was supported by chemosynthetic primary production in which microorganisms harnessed the abundant geochemical energy available in the hydrothermal fluids. This challenged one of the basic ecological premises that all ecosystems on Earth were dependent on light energy and driven by photosynthetic primary production.

Since those initial revelations, research efforts have focused on assessing the microbial diversity and attempting to understand the intimate associations between microbial productivity, geology, and geochemistry in marine hydrothermal environments. This article is a general discussion of the trends that are beginning to emerge from these efforts. Included in the discussion are overviews of the geologic setting of marine hydrothermal systems, the generation of hydrothermal fluids from different geologic settings, and the types of structures formed.

For additional in-depth reviews, the Geophysical Monographs published by the American Geophysical Union (AGU) are valuable resources (Humphris et al.,

1995; German et al., 2004; Wilcock et al., 2004; Christie et al., 2006).

Geological setting

Most seafloor hydrothermal vent systems are associated with extensional tectonic activity and heated by magmatic heat as it is convected into the crust (Seyfried and Mottl, 1995). The most well-studied areas of hydrothermal circulation are along divergent plate boundaries where basaltic seafloor is made and mid-ocean ridges (MOR) arise (Figure 1). Hydrothermal circulation along MORs results from the active heating of seawater that percolates through newly formed basaltic crust. Hydrothermal venting is also commonly found along convergent plate margins where an oceanic plate is subducted beneath a continental plate forming island arcs and back-arc basins (Christie and Fisher, 2006). Vents along back-arc basins are actively heated in the same way as those along MOR, although the fluids tend to be more heterogeneous due to the variability in magma composition and additional inputs from the subducting plate (GAOM et al., 2006). A third location where seafloor hydrothermal systems can be found is at intraplate volcanic hot spots. Volcanic hot spot systems are not directly associated with tectonic plate margins, but are actively heated as plumes of molten magma push up through the mantle and crust (Seyfried and Mottl, 1995).

The recently discovered Lost City vent field more than 15 km off axis of the Mid-Atlantic Ridge (MAR) represents a new type of seafloor hydrothermal system as it appears to be at least partially heated by exothermic reactions between mantle derived peridotite and seawater (Kelley et al., 2001). These reactions have a dramatic impact on the composition of the hydrothermal fluids, which in turn affects the microbial community as discussed in the following sections. Although Lost City represents the first vent type of its kind discovered, similar systems are believed to exist along margins of slow- and ultraslow-spreading ridges where uplifting of ultramafic massifs are common.

Hydrothermal fluids

Seawater heated in contact with subsurface rocks dramatically alters the chemical composition of the end member fluids. The degree of alteration is influenced by several factors including the initial composition of the seawater, the type and structure of the host rock, the presence of sediment overlaying the host rock, and the type, depth, and size of the heat source (reviewed in Tivey, 2007). Understanding these interactions and how they affect the composition of hydrothermal fluids is important as the fluids set the physiological parameters and provide the metabolic menu for colonizing microbes. For comparison, representative compositions of hydrothermal fluids from different settings are presented in Table 1.

Basalt hosted hydrothermal fluids

Water–rock reactions begin as cold seawater infiltrates shallow basalt in the recharge zones (Figure 2). Initial low temperature reactions ($\leq 60^\circ\text{C}$) result in the removal of alkali metals from seawater and the oxidation of basaltic minerals (i.e., olivine and plagioclase), with the concomitant leaching of silica (Si), sulfur (S), and sometimes magnesium (Mg) from the minerals (reviewed in Alt, 1995). Magnesium is eventually completely removed from the fluids as Mg-rich clays precipitate at temperatures above 150°C . Anhydrite (CaSO_4) precipitation and seawater sulfate (SO_4^{2-}) reduction also occur in the recharge zone at temperatures above 150°C , resulting in the complete removal of SO_4^{2-} from the fluids. As the fluid continues through the crust, reactions with iron-bearing minerals such as olivine and pyroxene result in highly reducing fluids with elevated concentrations of hydrogen gas (H_2) (Tivey, 2007). Upon reaching the reaction zone where fluids are heated upward of 400°C , the fluid obtains its chemical signature by leaching S and metals (copper-Cu, iron-Fe, manganese-Mn, zinc-Zn) from the surrounding rocks (Alt, 1995). Phase separation

may also occur in the reaction zone if temperature and pressure are greater than 407°C and 298 bars, respectively (Von Damm, 1995). Phase separation can have a significant impact on the composition of end member fluids as volatiles such as hydrogen-sulfide (H_2S) tend to partition in the vapor phase while metals such as Fe become enriched in the liquid (brine) phase. Gases such as helium (He), methane (CH_4), and carbon dioxide (CO_2) may also be added to the hydrothermal fluids as volatiles from the underlying magma (Alt, 1995). In total, these reactions result in end member fluids that are acidic (pH 2.8–4.5), highly reduced, rich in H_2S and metals, and heated up to 400°C . The fluid is also extremely buoyant relative to seawater and is forced back to the seafloor through the discharge zone and may emerge as diffuse or focused flow depending on the degree of subsurface mixing during the ascent (Figure 2).

Other factors, such as differences in host rock and sediment cover, can contribute to the chemical composition of end member fluids. The impact that different host rocks have on fluid chemistry is best illustrated by the ultramafic hosted Rainbow vent field along the MAR

Hydrothermal Environments, Marine, Table 1 Representative chemical compositions of hydrothermal fluids from different geologic settings

Characteristic	Deep seawater	Mid-ocean ridge	Back-arc basin	Sediment hosted	Rainbow vent field	Lost City

Modified after Tivey (2007). *bdl* below detection limit

(Douville et al., 2002). Fluids from Rainbow vent field are lower in pH, have much higher Fe concentrations, are enriched in H₂ and CH₄, and are depleted in H₂S relative to fluids from most MOR systems (reviewed in McCollom, 2007). These differences in composition are related to the same serpentinization reactions that fuel the Lost City vent field (see below) although the heat sources differ. Sediments overlying the host rock can also affect the composition of end member fluids (German and Von Damm, 2004). In general, sediment-hosted systems generate fluids that are higher in pH (5.1–5.9) and lower in metal contents than those from unsedimented systems. Chemical differences largely depend on the amount and type of organic matter present in the sediments (Tivey, 2007).

Lost City hydrothermal fluids

Hydrothermal fluid generation at Lost City begins much in the same way as fluid generation at MOR systems, with the infiltration of seawater into rock. However, the rock is not basalt but rather mantle-derived peridotite which reacts with seawater to form serpentinite (Kelley et al., 2001). Serpentinization reactions result in the hydration of minerals such as olivine and produces large amounts of heat, H₂, and CH₄. This heat is believed to at least partially drive hydrothermal circulation at Lost City although other heat sources have been suggested (Kelley et al., 2001; Allen and Seyfried, 2004). Regardless of the heat source, the end member fluid chemistry is dramatically different than MOR vent systems and is indicative of seawater–rock reactions below 150°C. The most striking differences are the alkaline pH (≈10–11), the lower temperatures (up to 93°C), the elevated calcium (Ca) content, and the low concentrations of metals and H₂S found

in the fluids (Kelley et al., 2001, 2005). Methane and H₂ concentrations are also elevated relative to basalt-hosted MOR systems (Table 1).

Hydrothermal structures MOR sulfide deposits

When acidic hydrothermal fluids rich in reduced chemical species interact with cold, oxygenated seawater, minerals rapidly precipitate out of solution forming large deposits (reviewed in Juniper and Tebo, 1995). Mineral phases found in these deposits include sulfides, sulfates, oxides, hydroxides, silicates, and carbonates. Deposit formation can occur in the subsurface as the fluids ascend through oceanic basalt and mix with infiltrating seawater or directly on the seafloor as high temperature fluids erupt into bottom seawater. Subsurface precipitation of minerals generates stockwork deposits in the shallow crust and results in low-temperature venting on the seafloor. Low-temperature fluids are generally low in metal sulfides and as a result, precipitate oxides upon reaching the seafloor. In contrast, fluids that have not been diluted and cooled in the subsurface rapidly precipitate metal sulfides such as pyrite (FeS₂), chalcopyrite (CuFeS₂), and sphalerite (ZnS) upon mixing with seawater. Precipitation of metal sulfides results in the appearance of “black smoke” and ultimately forms massive sulfide deposits (>60% sulfide minerals). Several types of sulfide features are found in vent fields, with the most spectacular being the black smoker chimney (Figure 3a). Other sulfide structures generated at marine hydrothermal vents include diffuse flow beehives, flanges, and complex flow sulfide mounds (Van Dover, 2000). In all cases, active sulfide features provide extreme physical and geochemical gradients that

Hydrothermal Environments, Marine, Figure 2 Hydrothermal circulation along MOR depicting compositional changes of seawater and microbial habitats supported by hydrothermal fluids. *Small arrows* indicate fluid flow while *large arrows* indicate heat transfer from magmatic source. Image is not to scale. Adapted from Reysenbach (2001).

sustain diverse microbial populations even after fluid flow has ceased.

Lost City carbonate deposits

In contrast to the sulfide structures found along basalt-hosted MOR systems, hydrothermal fluids venting at Lost City produce large white chimneys and flanges composed primarily of aragonite (CaCO_3) and brucite ($\text{Mg}(\text{OH})_2$) (Figure 3b) (Kelley et al., 2001). Active structures are highly porous and emit fluids from complex networks of centimeter sized channels (Kelley et al., 2005). Extinct structures are less porous resulting from the replacement of aragonite with calcite (CaCO_3) and the dissolution of brucite. The largest structure at Lost City, Poseidon, is over 60 m tall, making it the tallest seafloor hydrothermal feature yet discovered (Kelley et al., 2001).

Microbial metabolism

The hydrothermal fluids provide the energy and nutrients for a thriving microbial ecosystem. Additionally, the porous sulfide deposits are excellent habitats for the metabolic diversity of microorganisms.

Terminology

Energy sources for microbial metabolism include light-dependent reactions (less important at deep-sea vents) and light-independent chemical reactions and are described by the prefixes photo- and chemo-, respectively. Energy sources are further classified depending on whether the source of electrons is inorganic (-litho-) or organic (-organo-). For carbon sources, the suffix -autotroph describes an organism that obtains carbon from an inorganic source (CO_2), while the term -heterotroph describes an organism that obtains carbon from an organic source. For example, a microorganism that is able to gain energy and electrons from H_2 and use this energy to fix CO_2 is referred to as a chemolithoautotroph, while humans who require organic carbon and energy sources are described as chemoorganoheterotrophs, as are many microorganisms. Some microorganisms are not obligatory autotrophs and will assimilate organic carbon substances if they are available. The term mixotroph is used to describe these organisms which appear to be common in most environments.

Microorganisms also have varying requirements for oxygen (O_2) as an oxidant. Some organisms have an
